TABLE 1. *Vehicular fatalities by type of accident in U. S. Navy and Marine Corps personnel in U. S. Government vehicles only (1952 through 1954)*—Continued

-
- a. In one fatal accident, a passenger was thrown out and escaped with spinal injuries.
 - b. Jeep, rolled over, killing passenger; driver was thrown out and escaped injury.
 - c. In one fatal accident, eight other passengers in back escaped injury.
 - d. In one fatal accident of each type, others in vehicle who were not thrown out were only slightly injured.
 - e. Drowned when vehicle ran off pier or turned over in shallow water.
-

Two vehicular deaths not tabulated occurred on aircraft carriers at sea. In each of these, an aircraft towing truck fell into an elevator well, the driver falling first and the truck on top of him. They are not included in the tabulation, as speed and design of this vehicle would not seem to call for use of seat belts.

these same 33 persons would have been killed had they been kept in the vehicle by seat belts, although in a number of instances they actually were thrown out before being pinned down or rolled on.

On the other hand, in 13 of the 20 deaths in accidents of panel and pickup trucks, carryalls, and other hard-top vehicles, the chances that a seat belt would have prevented the fatality appear to have been very good. In 12 cases the victim was thrown out of the cab or enclosed part of the vehicle; however, in one of these he was probably too drunk to have used a belt, leaving 11 who might have been saved. In four of the accidents the victim was fatally injured while remaining in the cab; however, in one case he was crushed by the steering wheel and in another he probably was too drunk to have used a belt, leaving 2 more who might have been saved. In three deaths the victim was drowned when the vehicle turned over into a rice paddy or plunged off a pier; and the remaining man killed was sitting on the rear of a pickup truck and was thrown out.

In the one ambulance accident involving a fatality, not only was the driver killed but also the passenger (a medical officer) was thrown about and critically injured. Considering that in 1950 another medical officer was killed in a Navy ambulance collision by being thrown from the right front seat, it would seem especially important to provide safety belt protection for the passenger on the front seat of a standard ambulance.

There were 14 deaths caused by falls from vehicles not involved in accidents. Seven of the victims were killed by falling from fire, crash, or gasoline trucks; usually when the truck was making a sharp turn. Two of these were passengers seated in the cab, and five were men standing on the truck, who lost their grip on a turn or while changing position. The two seated passengers certainly would have been saved by seat belts. It also would appear warranted to consider the use of quick-release belts to hold standees in place on certain types of fire and crash vehicles. Four of the 14 victims fell off the rear end or side rail of 6 by 6

In the one ambulance accident involving a fatality, not only was the driver killed but also the passenger (a medical officer) was thrown about and critically injured. Considering that in 1950 another medical officer was killed in a Navy ambulance collision by being thrown from the right front seat, it would seem especially important to provide safety belt protection for the passenger on the front seat of a standard ambulance.

There were 14 deaths caused by falls from vehicles not involved in accidents. Seven of the victims were killed by falling from fire, crash, or gasoline trucks; usually when the truck was making a sharp turn. Two of these were passengers seated in the cab, and five were men standing on the truck, who lost their grip on a turn or while changing position. The two seated passengers certainly would have been saved by seat belts. It also would appear warranted to consider the use of quick-release belts to hold standees in place on certain types of fire and crash vehicles. Four of the 14 victims fell off the rear end or side rail of 6'

trucks or dump trucks, and three died from falling between the frame and treads of caterpillars.

If seat belts had been installed in hard-top vehicles only, and if men had been successfully indoctrinated in using them (which will take considerable time and effort and never be fully achieved), a saving of 15 lives is the maximum benefit that could have been expected on mortality alone. If all these deaths had been prevented, the monetary saving would have amounted to over \$470,000. This is only the beginning of savings possible, as many grave and costly injuries would at the same time have been prevented or converted to minor ones.

The lack of adequate data in many reports of death is a serious handicap in estimating the value of preventive measures, either potential or realized. Even more sketchy is the data on injuries which are survived. The latter are far more frequent and often much more costly in time, medical manpower, and money, than deaths. Data of immense value for planning and for subsequent evaluation could be obtained if more detailed information were required on all automobile injuries involving more than a few sick days. A minimum of 5 or 10 days might be specified so as to keep the burden of reporting within reason. The causative vehicle, the method in which injury was sustained, the presence or applicability of safety devices, all need a statistical evaluation.

SUMMARY

Deaths of Navy and Marine Corps personnel in government-owned ground vehicles are analyzed for a three-year period. More than half of these (41 out of 72) occurred in open-top military type vehicles, a higher proportion than would be expected during peacetime. Provision of seat belts in open-top vehicles would probably not have reduced but would more likely have increased these fatalities. In only five deaths did this type of vehicle remain upright when involved in an accident, whereas in 33 it rolled over. By comparison, 10 persons who escaped death in rollover accidents by being thrown out would probably have been killed if they had been kept in by seat belts.

In hard-top vehicles involved in accidents, 15 of 20 deaths would probably have been prevented if the victim had been wearing a seat belt, although in two cases he was too drunk to have used one. In 12 of the deaths, the victim was thrown from the cab, with or without rollover. Front seat passengers in ambulances appear to be especially at risk when not provided with seat belts.

Seven deaths, or one out of 10, occurred in falls from fire and crash trucks when the vehicle was merely making a turn. In two of these, the man slid off a seat. In these two cases, seat belts

would certainly have prevented the accidents had they been worn. Quick-release bolts for standees should also be considered for this type of vehicle.

If seat belts are used in hard-top vehicles, potential monetary savings on deaths alone amount to \$470,000 in three years. In addition, many serious and costly injuries would be prevented.

Weighing the cost of preventive measures against their savings, both in deaths and in the far more frequent nonfatal but costly injuries, requires more detailed reporting of the causes of trauma in serious and fatal vehicular accidents.

THE NAVY — 1957

"The Navy will add six warships and five other vessels to the fleet during fiscal '57, but manpower will be decreased.

"Slated to end fiscal '56 on 30 June with 405 warships, the Navy has won Administration approval for 411 warships a year later and for 594 other ships—a total of 1105, compared with 944 planned for the end of the present fiscal year.

"The Navy will have the same number of carrier air groups, 17, and carrier anti-submarine squadrons, 31, at the start and end of fiscal '57.

"On the personnel side, newly announced plans will show the Navy beginning the year of 1 July with 662,744 officers and men, and ending the 12 month-period with 662,175.

"At the end of fiscal '57, the Navy foresees a strength level of 72,800 officers and 584,200 enlisted men, identical figures with those at the beginning of the year."

MINOR REFRACTIVE ERRORS VERSUS DEPTH PERCEPTION

BUTHER L. NEWMAN, *Lieutenant (junior grade), MSC, USN*

GOOD DEPTH perception is important to everyone, but as was pointed out when the visual screening profiles of a group of Overhaul and Repair Department inspectors at this air station were being reviewed, some who are in technical trades and professions need to excel in this particular visual skill. Because screening on depth perception was included in the routine checks along with far and near point acuity, far and near point muscle balance, and color perception, some interesting data were compiled. This is especially true of the findings on 17 men who initially failed the depth perception screening, but who passed on a second trial, after having been refracted and given a lens prescription (table 1). These data substantiate the opinion that refractive error and bad depth perception go hand in hand.

In the phenomenon of depth perception, many factors are combined before a final estimation of depth is accomplished. Although the time element involved in making an estimation is only a split second, a combined reaction to various stimuli has taken place in the observer's nervous system. For purposes of discussion, these stimuli can be called factors, and the factors classified as adjunctive (depending on the relative comparison of one outside object to another) and basic (depending solely on the observer's perception apparatus and the object under estimation). Adjunctive factors are: comparison of retinal image sizes of two familiar objects; motion parallax (*i. e.*, the apparent motion of objects within the visual field surrounding the object of fixation that is caused by movement on the part of the observer); linear perspective; and familiarity with the effects of atmospheric conditions on the appearance of distant objects. This last factor might be referred to as aerial image. Add to this the factor of accommodation (or range of focusing), and you have a fairly complete list of adjunctive factors affecting depth perception that are available to either one- or two-eyed individuals.

Since the best depth perception depends on factors which are available only to persons with binocular vision, and since this

article is wholly concerned with binocular subjects, let us consider what takes place in the case of such an observer who is hampered in estimating depth by some slight anomaly in the form of a minor refractive error in one or both eyes. The foremost factor in making a depth estimate that is affected by a refractive error is binocular parallax, by means of which the two eyes working in a binocular pattern can discern the movement of an object either toward or away from the object of fixation. This is possible because binocular subjects have available to their perception apparatus overlapping retinal fields, semidecussation of optic nerve fibers, corresponding points, and conjugate movements of the eyes. Unless visual acuity is approximately equal in the two eyes, the foregoing physiologic factors will not be nearly so effective in helping to make accurate depth estimates. Just what physiochemical, neurophysiologic, or gross anatomic changes are responsible for the phenomena that refractionists call refractive errors is still open for research, but since this article is reporting only the effects of refractive errors on depth perception, I will not attempt further discussion of the physiologic processes involved.

Of about 400 inspectors examined, 17 men ranging from 29 to 48 years of age were found to have substandard depth perception; yet their failing of the depth test on routine visual screening was the first intimation that anything was amiss in their visual apparatus. None would admit to having any subjective complaint with respect to visual acuity or visual discomfort. The fact that these 17 men would be able to pass every other screening test, so long as depth perception was not checked, points up the extreme desirability of including such a test in the routine visual screening of any age or occupational group. Were it not for their having failed on the depth check, these men would not have attained the increased visual efficiency which their subsequent lens prescription afforded them.

These 17 men were not the only ones whose scores on depth screening were below the standard set for Overhaul and Repair inspectors, but they were the only ones of these who had no objective or subjective sign of any visual defect other than faulty depth perception. That the percentage of the entire group examined who failed their depth screening was low was because even prior to the inclusion of the depth check in the screening routine, the men were periodically rescreened every six months, and appropriate changes were made in their lens prescriptions. Therefore, each could be considered to be at his peak efficiency insofar as visual acuity was concerned.

All but one of the 17 men had unaided monocular visual acuity of 20/20, the single exception having 20/20 O.D. and 20/40 O.S. There seemed to be no relationship among the 17 in regard to

That the percentage of the entire group examined who failed their depth screening was low was because even prior to the inclusion of the depth check in the screening routine, the men were periodically rescreened every six months, and appropriate changes were made in their lens prescriptions. Therefore, each could be considered to be at his peak efficiency insofar as visual acuity was concerned.

All but one of the 17 men had unaided monocular visual acuity of 20/20, the single exception having 20/20 O.D. and 20/40 O.S. There seemed to be no relationship among the 17 in regard to

the type of refractive correction needed, except that none were myopic. Some had simple hyperopia; others had variable types of astigmatism. One of the group required a short period of supervised orthoptics, in addition to his lens correction, to remedy a moderate amount of excessive exophoria. Upon rescreening after this treatment, he was able to pass the depth check. Age did not seem to have any significant relationship to failure on the depth check. The average age was 38 years only because there is little turnover in personnel among this particular group, with the natural consequence that the same group tends to be on the same job for a number of years.

SUMMARY AND CONCLUSIONS

The visual skill of depth perception can hardly be overstressed, and it is of paramount importance to include a depth check in any visual screening routine. Otherwise, the screening cannot be considered all-inclusive for evaluation purposes. This is illustrated by the finding of 17 men, among about 400 examined, who would be considered acceptable in any visual screening check were it not for their inability to exhibit a passable performance in depth perception. It appears important in the light of this experience that refractionists give careful consideration to any refractive error, no matter how small, as being a potential factor in causing a substantial decrease in visual efficiency.

GLAUCOMA PREVALENCE

"The National Society for the Prevention of Blindness estimates that approximately one million Americans have undiagnosed chronic simple glaucoma and states that every general practitioner should assume that one in 50 of his patients who are over 40 years of age probably has this disease." Early detection and treatment result in a favorable prognosis.

Malignant Palatal Lymphoma Involving the Periodontium

JAMES E. CHIPPS, *Lieutenant Colonel, DC, USA*

C. JULES ROMINGER, *M. D.*

WILLIAM D. SWANCUTT, *M. D.*

THE radiosensitivity of localized lesions in malignant lymphoma is well known. However, if there has been spread of the lesion to adjacent structures, usually some distant metastasis also exists and the benefits of local therapy are but short-lived.

The following case is of interest because the local involvement was marked, but there is no evidence of generalized disease or local recurrence 2½ years after irradiation therapy.

CASE REPORT

A 26-year-old man was returned from overseas with an ulcerating tumor of the oronasal structures, centering in the palate, which had been diagnosed as malignant lymphoma by biopsy.

History. Frequent episodes of acute nasal obstruction and sinusitis had occurred since the patient was 12 years old. There had been a sudden onset of left-sided earache and tinnitus 10 months before admission. The maxillary sinuses had been irrigated three months before, producing much purulent, foul-smelling material. Shortly afterwards, pain and swelling began in the roof of the mouth, and an ulcer appeared in the soft palate. The patient was hospitalized and treated with antibiotics. The swelling and ulcer continued to enlarge, and biopsies were obtained on separate occasions from the margin of the ulcer, the nasopharynx, and the tip of the inferior turbinate. Pending the results of the biopsies, cortisone and corticotropin (ACTH) were employed but without effect. A report of malignant lymphoma was obtained, and the patient was transferred from the overseas hospital to the zone of interior.

The transfer was completed on 5 October 1953. In the preceding few days, the patient had noted a rapid increase in the size of the ulcer, the swelling of the soft palate, and symptoms of nasal obstruction. In the preceding three months, there had been a 25-lb weight loss, which he attributed to an inability to masticate and a loss of appetite because of the foul-smelling oral ulcer.

1. The patient appeared chronically ill. A tumor mass of the nasopharynx and partially occluded the oropharynx so inspiration by mouth was slightly labored. The tumor mass measured approximately 9 by 5 cm, and a central area of ulceration measured by 2 cm. The lesion involved the entire hard and soft palate (figs. 1 and 2). The uvula was enlarged to twice its normal size. There was

Figure 1. Anterior portion of ulcerative lesion, hard palate.

Figure 2. Posterior portion of ulcerative lesion, soft palate and oral pharynx.

tumorous extension to the left tonsil and the upper pole of the right tonsil. A communication through the necrotic ulcer between the mouth and the floor of the right nasal cavity could be demonstrated by probe. All maxillary teeth were slightly mobile, although the marginal gingivae were at normal levels and the epithelial attachments had not receded. Nodes were palpable and tender deep to the mandibular angles bilaterally.

Radiographs showed destruction of the medial portion of the hard palate, opacity of the maxillary sinuses, and a polyp in the right frontal sinus.

Radiographs of the chest were normal, and the rest of the physical examination was not significant.

Treatment. The patient was presented to the hospital's tumor board. Irradiation therapy after extraction of the maxillary teeth was recommended.

Under general anesthesia on 6 October, a biopsy specimen was obtained from the edge of the palatal ulcer, and the dental extractions were accomplished. Although no attempt was made to include surrounding blocks of the maxillary bone in the routine forceps removal of the teeth, spongy white material which contained bony spicules clung to the apical half of each tooth as it was removed. An alveolectomy sufficiently extensive to permit approximation of the mucoperiosteal edges across the sockets was performed as a protective measure against the effects of irradiation.

Microscopically, the biopsy specimen from the palate (fig. 3) showed masses of atypical lymphocytes within the intratrabecular areas of cancellous bone. These lymphocytes presented a monotonous uniformity. There were no giant reticulo-endothelial cells. There was erosion of bone. A few fat cells were seen, but most of the fatty tissue was obliterated by the infiltrating tumor cells. A diagnosis of lymphosarcoma was made.

One of the extracted teeth with attached tissue was decalcified and sectioned. There was a diffuse infiltration of atypical lymphocytes in the tissue adjacent to the tooth root (fig. 4). Fragments of alveolar bone showed compression and erosion. Erosion of the cementum was seen in one area.

Irradiation therapy was accomplished between 7 October and 18 November, using the following factors: 200 kv, 20 ma, 50 cm target skin distance, Thoraeus filter half-value layer 1.95 mm Cu. Multiple portals were employed which encompassed the entire nasopharynx, all of the paranasal sinuses, and the lymph nodes in the upper cervical regions (fig. 5). A tumor dose of 3,000 roentgens was administered to all of these regions. Following this, additional treatment was delivered to residual tumor in the palate using a peroral lead cone and the following factors: 200 kv, 20 ma, 40 cm target skin distance, 0.5 mm plus

Figure 3. Microscopic section from hard palate showing atypical lymphocytes and bone erosion. ($\times 100$)

1.0 mm Al filter half-value layer 0.9 mm Cu, 1,500 r (in air). This raised the total tumor dose in the palate to 4,500 roentgens.

The patient tolerated this course of treatment well. The eyes and the oral commissures were protected by 4 mm of lead during the treatments. A second-degree erythema developed externally (fig. 6), and an ulcerative reaction developed in the palate. As the tumor regressed, there was a residual oronasal fistula at the junction of the hard and soft palate (fig. 7). By 14 December, all reactions had healed. There were no enlarged lymph nodes in the neck, and there was no evidence of residual neoplasia. The patient had gained 20 pounds during the treatment, and his general condition was good.

Course. A maxillary denture was constructed, which also served as a temporary obturator for the oronasal fistula. The patient was given physical disability discharge from the Army in April 1954 and subsequently observed at a Veterans Administration hospital at regular intervals.

Except for a chronic postnasal discharge there were no positive findings until January 1955, when radiographs disclosed a possible mass in the left maxillary sinus. A Caldwell-Luc procedure was performed on 21 January. The maxillary sinus was found to be free of masses. Multiple biopsies were performed, which revealed chronic

sinusitis but no evidence of recurrence of malignancy. Following this operation, an oroantral fistula developed. After one unsuccessful attempt at closure, the fistula was surgically closed in December. No recurrent malignancy was noted in either procedure.

In March 1956, a routine follow-up examination was again negative for recurrent malignancy. Examination at regular intervals will continue.

COMMENT

The lymphatics of the palate and the nasopharynx are the possible sites of origin in many reported cases of malignant lymphoma, and frequently there is a history of prolonged paranasal infection. When bone is involved in lymphosarcoma, such involvement is indicative of spreading rather than early disease.

In this case, the spread of disease was manifested by the perforation of the hard palate, loosening of teeth after replacement of the normal periodontium by tumor, fixation of the soft palate, fixation of the tonsils, enlargement of the upper cervical nodes, occlusion of the nasopharynx by a mass, and radiographic evidence of paranasal sinus involvement. Considering this regional spread and the nature of lymphosarcoma, a modified program of therapy directed at relief of symptoms was considered but rejected in favor of the attempt at curative therapy. The apparent absence of local recurrence or generalized disease after 2½ years is encouraging.

Volkman's Contracture of the Lower Extremity

A Complication of Patellar Tendon Transplantation

WALTER R. MILLER, *Captain, MC, USN*

WHENEVER an untoward incident occurs during a surgical procedure, there is an understandable reticence on the part of the surgeon to publish the case. If such information is given proper dissemination, however, it may assist in the recognition of premonitory signs in other patients, and possibly in the amelioration of residual damage. The following is such a case.

CASE REPORT

A 17-year-old girl student, seen as an outpatient, complained of falling several times a week because of bilaterally dislocating patellas. This had been occurring for a number of years, but recently had become more frequent and, in view of her age, more embarrassing. Examination corroborated the diagnosis. The left patella could be completely dislocated off the lateral femoral condyle when the knee was in approximately 40° of flexion. The right patella could be subluxed only. Roentgenograms confirmed the suspicion that both lateral condyles were lower in profile than normal.

Transplantation of a bone block including the left patellar insertion was performed on 28 February 1952. The block was moved medially and slightly distally, and secured with a stainless steel screw. The usual freeing of the lateral aspect of the extensor mechanism was done, and followed by reefing along its medial border. In spite of having been dislocated frequently, the patella, although somewhat smaller than normal, presented an articular surface covered with normal, glistening cartilage. It rode in an accessory groove in the lateral condyle completely apart from the intercondylar notch. The medial femoral condyle was hardly recognizable as such. It was deformed and although it was partially covered with cartilage, the cartilage was covered with synovial membrane.

The completely uneventful procedure, which required 1 hour and 10 minutes from initial incision to skin closure, was accomplished under spinal anesthesia and with a pneumatic tourniquet of the Campbell-

Boyd type inflated to 480. The tourniquet was applied to the thigh but not inflated until after preparation of the skin, and spiral application of an Esmarch rubber bandage. Thus the tourniquet pressure began not more than five minutes prior to the incision. Following the operation, a long leg cast was applied over ample sterile sheet wadding, after which the tourniquet was deflated and removed. Total tourniquet time was slightly less than 1 hour and 30 minutes. Good color and warmth returned to the toes immediately. The patient was taken to the ward in good condition and the casted leg was elevated on several pillows. About eight hours postoperatively, the surgeon was called by the surgical watch officer, who stated that the patient was having some pain in the leg but that the color and temperature of the toes were satisfactory. The surgeon recommended that the cast be split and spread slightly. There were no more phone calls that night, and it was believed that all was satisfactory.

The following morning at 1000 the patient was writhing with pain, although her operated leg from which the cast had been completely removed appeared essentially normal. Color of the leg and foot was good, and the temperature was equal to that of the other leg. Capillary return time in the toes was good, but neither posterior tibial nor dorsalis pedis pulsations could be felt and no oscillations were obtained by oscillometer except above mid thigh, where they were normal. The calf muscles were firm and somewhat tender, and the foot was in moderate equinus. The foot could not be dorsiflexed even to neutral, and much discomfort was caused by the attempt. The patient was quite clear in stating that her severe pain was in the entire leg from the site of the tourniquet distally. The tourniquet site in mid thigh was very tender, more so than any other area.

Hypesthesia to anesthesia started 4 inches below the knee joint over the lateral aspect of the leg and about 8 inches below the knee joint on the medial side, the two areas joining anteriorly about 7 inches above the ankle joint. The skin over the calf and foot was almost completely anesthetic.

Consultation with the neurosurgeon and the anesthetist resulted in the use of continuous caudal block with Pontocaine (brand of tetracaine hydrochloride). This promptly relieved pain and caused the leg to be somewhat warmer than the unoperated leg. The patient also volunteered: "The leg feels like it's mine now down to just above the ankle." An oxygen tent used only for cooling was placed over the leg and the temperature maintained between 75° and 80°F.

On the following day consultation among the chiefs of the orthopedic surgical, general surgical, and neurosurgical services and two civilian consultants (neurosurgery and orthopedics) resulted in recommendation for lumbar sympathectomy. Following this procedure the leg was cradled in cotton in balanced suspension. The operative incision was unremarkable. The leg, including the heel, was warm, but the foot remained cool and pulseless although capillary return was adequate. Pain was reduced to moderate discomfort.

On about the third day, the calf muscles had reached a maximum of almost woody hardness and the picture of Volkmann's ischemic contracture was well developed. A small, quarter-sized area of blackened skin appeared on the heel, together with a small, blistered area overlying the tendinomuscular junction of the Achilles tendon. These both disappeared during the next two weeks.

In spite of gentle but persistent physiotherapy, followed later by a low leg brace with dorsiflexing foot spring, the foot over the next three months assumed a position of equinovarus of moderate severity (30° of equinus). The operative wound healed without event. The patient could do a straight-leg raise with the knee locked in full extension in $4\frac{1}{2}$ weeks postoperatively, and the patella was felt to ride medially in a normal position. Six months following operation she had a full range of motion in the operated knee, without effusion. The foot could be voluntarily dorsiflexed to about 20° below neutral and everted to neutral. There was gross tightness and some residual induration in the posterior calf muscles; however, there was evidence of slight return of function in these. The level of hypesthesia had moved distally at least 5 inches, but the entire foot was still anesthetic. Physiotherapy, including heel cord stretching, was continued and the patient was wearing a brace part time while waiting until surgical correction of the foot deformity would be indicated.

DISCUSSION

The contracture I have described followed a relatively simple orthopedic operation on the anterior aspect of the leg performed under a properly applied pneumatic tourniquet. Search of the English literature revealed no other case of Volkmann's contracture of the leg following operation on the lower extremity, aside from a number of cases occurring as a complication of fracture of the femur. The condition is mentioned as a possibility by several authors while discussing the problem in the upper extremity.

To review in retrospect the situation as it confronted the operator at 10 o'clock on the morning following the operation, it was clear that splitting of the cast had not relieved the patient. Although she had required only two hypodermic injections of 10 mg of morphine and 60 mg of codeine during the first 20 hours postoperatively, she had complained of severe pain in the leg and of numbness in the foot and toes to such an extent that the entire cast had been removed in the early hours of the morning. At this time, according to the nurse's notes, "the toes and instep were blotched and blue." These were premonitory signs that could have been recognized and reported to the responsible surgeon. Whether earlier application of methods to reduce vascular spasm would have been effective in averting the residual damage will remain unknown, but it seems likely.

Much difference of opinion exists concerning when to explore the vessels in this condition. It was the opinion of those consulted in this case that since no trauma other than broadly distributed pressure from a pneumatic tourniquet had been inflicted on neurovascular structures, adequate blocking of the sympathetic outflow would be as effective or more so than operation in relieving vascular spasm. This view is supported by the report of Thomson and Mahoney¹ who state: "It seems significant that of all cases treated with sympathetic block (spinal anesthesia) only one was a failure and six were cured—muscle decompression with or without arterial exploration has proved to be of no value."

The opinion of Myerding² is of significance in cases that may become the subject for litigation: "Volkmann's ischemic contracture may result from injury when bandages, splints or casts of plaster of paris have not been used; this is a highly important fact, from a medicolegal point of view . . . I should like to emphasize again the great importance of the fact that Volkmann's ischemic contracture may result when there is no fracture and when no splint, bandage or cast has been applied."

SUMMARY

A case of Volkmann's contracture of the lower extremity following a relatively simple orthopedic procedure is presented. No report of a similar case could be found on search of the English literature. Early recognition of premonitory signs and symptoms of this complication is of the greatest importance, so that early treatment can be instituted and residual damage be reduced to a minimum.

Situs Inversus of Gastro-intestinal Tract

Complication by Partial High Intestinal Obstruction

RICHARD R. PICHEL WARNER, *Captain, USAF (MC)*

TRANSPOSITION of the stomach alone, or with situs inversus of all the infradiaphragmatic viscera, is ordinarily asymptomatic although sometimes associated with eventration of the right diaphragm.¹ Situs inversus of the intra-abdominal organs occurs once in every 6,000 to 8,000 individuals² and is more common than partial transposition or incomplete rotation of a portion of the gastro-intestinal tract. The latter condition, however, frequently produces symptoms, and the majority of such patients are brought to medical attention during early infancy. Occasionally an individual who has symptoms resulting from anomalous rotation of a portion of the gastro-intestinal tract will not seek medical attention until early adulthood because his symptoms may have been mild, although chronic. Only in recent years has it been appreciated that such congenital anomalies need not produce clinical manifestations until early adult life.^{3,4} Since the majority of military personnel are in this age category, the military physician should be acquainted with the symptoms and realize that such conditions may occur in young adults, and are not exclusively confined to infants and children.

EMBRYOLOGY

In order to understand the genesis of the group of conditions resulting from faulty rotation of the gastro-intestinal tract, it is necessary to have an understanding of the main features of the process whereby the gastro-intestinal tract attains its final asymmetrical arrangement.^{3,5}

The digestive tract of the embryo is divided into a foregut, midgut, and hindgut. The midgut extends from the third portion of the duodenum to the midtransverse colon. Distal to this area is hindgut, and proximal to it is foregut.

At the fourth week of fetal life, the primitive gut hangs in the midline supported by a common dorsal mesentery. A fusiform dilatation, the future stomach, appears, and just below this the liver diverticulum and the bud that gives rise to the pancreas develop. The primitive stomach becomes further dilated so that

its right surface is directed backward with the greater curvature facing downward and to the left. Due to this rotation, the liver and pancreas are carried from the midline to their respective final positions. If the stomach and descending portion of the duodenum rotate to just the opposite position from that described, the liver, pancreas, and spleen will then be carried along and be situated in such a way that they present a mirror image of their normal positioning; *i. e.*, *situs inversus*.

While the development and rotation of these portions and growths from the foregut are occurring, development and migration of the midgut is also underway. The midgut is divided into a pre-arterial portion, which extends from the third portion of the duodenum to the vitelline duct, and the postarterial portion, which extends from the vitelline duct (or Meckel's diverticulum) to the midtransverse colon. Between the sixth and tenth weeks the gut grows too rapidly for the celomic cavity to accommodate it. This results in the protrusion of a part of the midgut into the base of the umbilical cord (fig. 1A). By the tenth week, however, the peritoneal cavity becomes large enough to contain this portion of the midgut, and it is withdrawn from the base of the umbilical cord. As it enters the abdomen, it rotates in a counterclockwise direction so that the postarterial portion of the midgut (the segment from vitelline duct to midtransverse colon) is situated in the left side of the abdomen. This anticlockwise rotation continues after the midgut is entirely within the abdomen so that the cecum, which initially is in the left midabdomen, migrates to the left epigastrium and thence to the right epigastrium (fig. 1B), and finally swings around to its adult position in the right lower quadrant. The cecum and ascending colon then acquire their peritoneal reflections and attachments in the right side of the abdomen. At the same time, the small bowel, which also has been rotated in a counterclockwise direction, becomes firmly attached to the posterior abdominal wall by its mesentery.

Figure 1. Embryology. (A) Protrusion of a portion of the midgut into the base of the umbilical cord at 6 to 10 weeks' stage of development. (B) Midgut has re-entered abdomen at 10 to 12 weeks' stage of development and has undergone partial counterclockwise rotation so that cecum lies in right upper quadrant. This rotation will normally continue and will carry the cecum to the right lower quadrant, its final position.

artery
2-Umbilical orifice

- 3-Vitelline duct
4-Cecum
5-Descending colon

midgut may not occur. Most of the midgut, and particularly the postarterial portion, may still go to the left side of the peritoneal cavity upon entering the abdomen, but then the process of counterclockwise rotation may not go to completion, perhaps because of the large liver mass located in the left upper quadrant. This may then result in the cecum and most of the colon being located in the left side of the abdomen; the cecum may be mobile, and there may also be nonfusion of the mesentery of the midgut so that the small bowel hangs on a pedicle of the superior mesenteric artery.

Therefore, three types of abnormalities may occur to the midgut in association with or without situs inversus of the stomach and liver: (1) return of the midgut to the abdomen without any rotation;

2 inches in height and weighed 170 pounds. His usual weight had been 195 pounds. Vital signs were normal. Hydration was only fair. There was a prominent sternum and a slight pigeon-breast type of sternal deformity. The remainder of the physical examination disclosed no significant abnormalities.

Laboratory Findings. Peripheral blood studies at the time of admission revealed a red blood cell count of 3.7 million per μ l; hemoglobin was 11 g per 100 ml; hematocrit, 52.5 ml per 100 ml; reticulocyte count, 1.1 per cent; and white blood cell count, 13,400 per μ l with a slight shift to the left. The stool contained traces of occult blood. Urinalysis showed no abnormalities. Determinations of the fasting blood sugar, serum chlorides, and basal metabolic rate all yielded values within normal limits. The gastric contents after fasting contained 65° of free acid, and after histamine, 90° were present. An electrocardiogram showed no significant abnormalities. A roentgenogram of the chest was normal. The heart was in its normal position on the left. No defects in the diaphragms were noted. An upper gastro-intestinal series demonstrated situs inversus of the abdominal organs and an anomalous course of the duodenum. There was spasm of the pylorus and the duodenal bulb could not be well outlined. No deformity or ulcer crater could be seen. Several more upper gastro-intestinal series and roentgenograms of the small bowel were taken with the intent of studying the anomalous duodenum in detail. Barium was introduced by Levin tube in one of these studies. The duodenal bulb was well visualized and showed no deformity or ulceration. The anomalous course of the duodenum was well demonstrated (fig. 2), and considerable dilatation of the bulb and first portion of the duodenum was seen. A point of obstruction was visualized low in the descending limb of the duodenum (fig. 3). At this point, the transverse mucosal folds were converted into vertical striations. There was delayed passage of barium past this point. The picture was felt to represent partial obstruction due to extrinsic pressure as might be caused by a mesenteric band. Beyond this area, there was a reversed loop of the duodenum before it passed into the proximal jejunum, which went high and posteriorly on the right side of the abdomen. The cecum was low on the left side of the abdomen. A congenital anomaly of the lumbar spine consisting of failure of segmentation of L5 and S1 was present. An intravenous pyelogram showed two normal kidneys and ureters.

Course in Hospital. The patient was initially maintained on a nutritious liquid diet and antacids. After two weeks, symptoms of obstruction disappeared and he was allowed a more nearly regular diet. His work-up was completed, and on 9 June 1955 he was operated on.*

At operation, as seen on the roentgenograms, his abdominal viscera were completely transposed from left to right in a mirror image of the normal arrangement. The cecum was completely mobile and the small

*Operation was performed by Capt. Gilbert L. Chamberlin, USAF (MC).

Figure 2. Roentgenogram demonstrating situs inversus of the stomach and anomalous course of duodenum.

intestine's mesentery was attached to the posterior abdominal wall for only eight centimeters. The appendix contained several fecaliths. The jejunum and ileum were normal as was the ligament of Treitz. The duodenum was elongated to about 15 inches and was enveloped in peritoneal folds, which at the most dependent portion of the duodenum had kinked this loop of gut in a sharp 180° angle. This point of sharply angulated gut was just below the attachment of the duodenum to the pancreas. From this point, the duodenum crossed itself, ran laterally upward and back across itself again, and then posteriorly to the superior mesenteric artery to reach the ligament of Treitz. Two normal kidneys were present, but a right retroperitoneal mass was noted and proved to be an accessory kidney. The duodenum was mobilized and its kinked dependent portion was straightened out by freeing it from the enveloping mesenteric folds. It was felt that this would be sufficient to relieve the patient's symptoms of recurrent partial intestinal obstruction. The appendix was also removed.

Postoperatively, the patient's convalescence was entirely uneventful, and three weeks after surgery he was returned to duty. When seen three months later, he was entirely free of gastro-intestinal symptoms and eating a regular diet.

Figure 3. Roentgenogram demonstrating considerable dilatation of the duodenal bulb and first portion of the duodenum, with point of partial obstruction in descending limb of duodenum just proximal to sharp angulation.

It was believed at the time of operation that, although incomplete, the attachment of the small intestine's mesentery to the posterior abdominal wall was sufficient to render the possibility of volvulus unlikely. Therefore, no attempt was made to immobilize the small bowel by further attaching its mesentery. The increased incidence of duodenal ulcer in association with partial obstruction at the duodenum due to congenital bands or adhesions⁷ was appreciated. Hence, roentgenographic studies were meticulously performed in the search for an ulcer. Such ulcers are felt to be due in large part to stasis. Our patient may have had such an ulcer in the past or at the time of admission, and its bleeding would explain the mild anemia and occult blood in the stools found when he was hospitalized. Such an ulcer at the time of admission could have been a very superficial one and could have healed prior to operation. In such ulcer cases, since stasis is the major causative factor, the surgical relief of the duodenal obstruction is usually sufficient to result in cure.

THE FOUR STAGES OF KNOWLEDGE

"Where are we in our efforts to understand arteriosclerosis? Well, certainly not very far. Discovery in general can, I think, be divided into four stages. The first is the period of uncoordinated fact collecting—the naturalist or "butterfly net" period. This is the period of magnificent indifference; in it lie the seeds of discovery but the inner structure is barely discernible. The second is the period of controversy—the "rhubarb stage" of the ball game. This stage is often called one of "scientific controversy" to make it sound less like the rhubarb that it really is. It has the merit that there is probably something worth arguing about if this stage is reached. It is healthy so long as young investigators understand its nature and not take it, or themselves, too seriously. The third is the period of definition and clarification—the "white of an egg stage" because someone clarifies the problem by precipitating the irrelevant sediment. The fourth and last is the period of solution or fruition—the "bravo stage" in which everyone, or nearly everyone, agrees, applauds and goes home and from then on nobody does much more about it, except in some rare cases, collects royalties.

"I think you will agree that research in arteriosclerosis stands about half way between the first and second stages."

Departments

A MESSAGE FROM THE A. M. A.

A recently published letter from an anonymous captain received wide circulation among military personnel. The correspondent attempted to establish that the basic cause of the acute shortage of doctors in the armed services is that there are simply not enough available physicians in this country. To support his opinion, the captain accused the American Medical Association of limiting the number of medical schools as well as the number of licensed physicians. Specifically, he charged that (1) the A. M. A. began a policy 50 years ago of closing down medical schools; (2) only 1 out of every 10 or 20 applicants is admitted to a medical school; and (3) the A. M. A. started a policy of refusing to permit Americans who are graduates of European medical schools to take state medical board examinations.

Statements like this are not new, and unfortunately they have been repeatedly made in public print. Are they fact or fiction? Well, let's examine the record and see.

As to the first charge, *the American Medical Association has never closed any medical school*. In fact, it has neither the authority nor the desire to control the growth of medical schools. Some 56 years ago, a report on the unsavory quality of medical education in the United States was published as a result of a study spearheaded by Dr. Abraham Flexner. The report clearly revealed that only about one third of the schools then in existence were offering a satisfactory medical education adequate to meet the needs of that period. The report shocked reputable medical educators, and their actions brought speedy results. A vigorous house cleaning ultimately wiped out about two hundred fly-by-night schools which were either diploma mills or had facilities, personnel, or financing inadequate to offer a medical education suitable for that period. From 1910 until about 1928, medical schools were classified as A, B, or C in terms of their over-all potentialities; B or C schools either improved or closed their doors. This type of classification was discontinued in 1928, and since that time medical schools have been approved or not approved.

The American Medical Association Council on Medical Education and Hospitals has worked closely with the Association of American Medical Colleges in constant efforts to assist in developing and maintaining sound standards of medical education

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.—
Editor.

in the United States in the interests of the American public, which the graduates of our medical schools must serve. These two organizations have exerted great influence in medical education. They have co-operated in stimulating and encouraging new medical schools, and have assisted in the improvement of those in existence by establishing sound, basic essentials of medical education, as well as by consultations, advice, and survey evaluation.

The number of approved medical schools in the United States increased from 66 in 1910 to 81 in 1955, a growth of 22.7 per cent. On the basis of new schools now under development, the number will have increased 30 per cent by 1960. In 1955, there were 28,583 students enrolled in medical schools as compared with 12,530 in 1910. The number of physicians graduated from approved medical schools since 1910 has far outstripped the growth of the over-all population of the United States. While our general population was increasing 80 per cent, the supply of doctors increased 120 per cent. Today, we have not only more doctors, but far better care than a generation or two ago. Physicians now treat a great many more patients and treat them more efficiently.

The second charge is likewise incorrect and not supported by the facts. Simple arithmetic establishes that *over half of all applicants were accepted into medical schools in 1953-1954 and in succeeding years*. The exact ratio of admissions to the number of applicants for 1953-1954 was 1 to 1.97, or 7,749 admissions out of a total of 14,678 applicants; for 1954-1955 it was 1 to 1.93, or 7,556 admissions out of a total of 14,538 applicants. Several years ago, publicity was given to the number of applications filed rather than to the total number of applicants filing them. This was incorrectly interpreted to mean that only 1 out of every 10 or 20 applicants is admitted to a medical school. The fact is that each applicant usually applies to some 2 to 4 or 5 medical schools. This means, of course, that the number of applications filed represents many times the number of people who are actually applying for admission to a medical school. For example, in 1953-1954 there were 48,556 applications for admission to medical schools, made by 14,678 individuals. Each applicant filed an average of 3.3 applications. Even at the peak period of admission to medical schools in 1948-1949, when large numbers of young men were being released from military service, the ratio of applicants to admissions was never higher than 3.6 to 1.

The third charge is a fallacy. By state statutes, it is the function and authority of the individual states to determine who shall practice within their borders, and to maintain high standards of medical practice in accordance with their respective rules and

regulations. The State Boards of Medical Examiners are independent agencies, and *the licensing in each state is done on the basis of the individual medical practice acts of the states concerned and the determinations of the various individual licensing bodies.* There are 20 medical licensing boards that permit licensure of foreign-trained physicians. On the other hand, foreign-trained physicians are not eligible for licensure by 12 boards. Special requirements for foreign-trained physicians are specified by 18 boards, while 16 boards have varying exemptions. In the final analysis, medical licensure in the United States is a "sovereign state right" that is entirely under the jurisdiction of the governments of the individual states.

The captain's suggestion for the creation of a medical academy to produce medical officers for the Armed Forces is not new. This idea has been carefully considered for a number of years by Congress, the military services, the medical profession, and groups of medical educators. All who have looked into the problem agree that, if the services are to produce their own physicians, it is far better and cheaper to subsidize the education of medical students in existing medical schools than for the Federal government to create, equip, and staff a separate medical academy. Furthermore, all groups agree that the present diversification in background and training of medical officers who have graduated from a number of different medical schools is a distinct advantage to military medicine.

Based on these decisions, the military services recommended legislation to the last Congress that would have permitted the subsidization of medical students under contract to become career military medical officers upon the completion of their training. This recommendation had the whole-hearted support of the medical profession.

Before Congress had completed final action on the proposal, however, the military services found it possible to establish a program of subsidizing the training of selected senior medical students in return for commitments of military service. This program is now in operation with the full support of the medical profession and medical educators. Studies are currently under way to determine the feasibility of extending this program to include junior medical students as well.

Programs of this type, together with the recently enacted career incentive bill for medical officers, should prove of great assistance in solving the basic problem.

EMINENT ARMY UROLOGIST DIES

Colonel James C. Kimbrough, MC, USA (Ret.), age 68, died on 19 August 1956 at Walter Reed Army Hospital, where he had served for the past 10 years.

From 1946 to 1953, he was chief of the hospital's Urology Service. In August 1953, upon retiring from the U.S. Army after 36 years of service, he was designated by an Act of Congress as consultant in urology to Walter Reed Army Medical Center, "... in recognition of the outstanding service and contribution made to the science of medicine and surgery... and to provide that his mature professional judgment and long experience may continue to remain available to the public service...."

A native of Madisonville, Tenn., he was graduated from Hiwassa College and from Vanderbilt University School of Medicine before entering the military medical service in July 1917. Since 1921, he served almost exclusively as chief urologist at various Army hospitals, including four duty tours at Walter Reed. He was also Chief of the Professional Services Division in the Office of the Chief Surgeon, European Theater of Operations, from 1942 to 1945.

In World War I, Colonel Kimbrough received the Purple Heart award, and a Meritorious Service Citation signed by General of the Armies John

J. Pershing. In World War II, he was awarded the Legion of Merit and the Bronze Star Medal. In 1952, he was awarded a plaque by the American Urological Association, of which he was a member, in recognition of his "contributions to the advancement of science and practice of urology" and for his "efforts in promoting pleasant working relations between civilian and military medicine," and in 1955 he was elected president of that association's Mid-Atlantic Section, the first time in the association's history that a former Army officer had held the position. Since his death the annual postgraduate refresher course in urology at Walter Reed has been named in his honor.

FIRST INTERNATIONAL CONGRESS OF NEUROLOGICAL SCIENCES

The First International Congress of Neurological Sciences will be held in Brussels, Belgium, 21-28 July 1957. This Congress is the first integrated international convention of all independent international congresses of several neurological disciplines. Meeting simultaneously in Brussels under the new co-ordinated program are Sixth International Neurological Congress, Fourth International Congress of Electroencephalography and Clinical Neurophysiology, Third International Congress of Neuropathology, First International Congress of Neurological Surgery, Third Meeting of the International League against Epilepsy, and Second Symposium Neuroradiologicum.

The scientific program will highlight two major symposia of common interest to the Congress: Extrapyrarnidal Disease, by Professor Raymond Garcin of Paris, and the Significance and Interpretation of Modifications of the Conscious State, by Sir Geoffrey Jefferson of London. Special interest symposia will include Multiple Sclerosis, under the Chairmanship of Professor H. Houston Merritt of New York.

Further information may be obtained from Dr. Pearce Bailey, Secretary, Committee for the United States of the Sixth International Neurological Congress, National Institutes of Health, Bethesda 14, Md.

DEATH

ALTEE, Miriam Elizabeth, Lieutenant, NC, USN, of Columbia, S. C.; Chief Nurse at U. S. Naval Air Station, Norfolk, Va.; graduated from the Petersburg Hospital School of Nursing, Petersburg, Va., 12 August 1937; appointed, Nurse, in the U. S. Navy and ordered to active duty 6 May 1940; died 24 August 1956, age 43, at the U. S. Naval Hospital, Portsmouth, Va., of metastatic carcinoma of the vertebrae.

Promotions of Officers

The following officers of the military medical services on active duty in the Army, Navy, and Air Force have recently received temporary promotions to the rank indicated.

MEDICAL CORPS

ACKERMAN, Gustavo A., Capt., USA

ANNUAL MEETING OF MILITARY SURGEONS IN WASHINGTON, D. C., NOVEMBER 12-14

The expanding horizons of military medicine will be the theme of the 63d annual convention of the Association of Military Surgeons of the United States which will be held at the Statler Hotel, Washington, D. C., from 12-14 November 1956. In addition to the program listed below, a record number of 14 technical and scientific exhibits have been planned for display throughout the meeting.

Monday Morning, 12 November

Presiding: Rear Adm. Winfred P. Dana, MC, USN, President

Association President's Address—Rear Adm. Winfred P. Dana, MC, USN, Assistant Chief for Aviation and Operational Medicine and Research and Medical Military Specialties, Bureau of Medicine and Surgery, Department of the Navy.

Welcoming Remarks—Edward H. Cushing, M. D., Deputy Assistant Secretary of Defense (Health and Medical).

Guest Speaker—Detlev W. Bronk, Ph. D., President, National Academy of Sciences.

Expanding Horizons: Career Incentives—Rear Adm. Bruce E. Bradley, MC, USN, Acting Surgeon General, Department of the Navy.

Medicare Law—Maj. Gen. Silas B. Hays, MC, USA, Surgeon General, Department of the Army.

Expanding Horizons of Aviation Medicine—Maj. Gen. Dan C. Ogle, USAF (MC), Surgeon General, Department of the Air Force.

Expanding Horizons: Teamwork in Civilian and Military Health Services—Leroy E. Burney, M. D., Surgeon General, U. S. Public Health Service, Department of Health, Education, and Welfare.

Expanding Horizons in Research and Education in the Veterans Administration—Roy A. Wolford, M. D., Deputy Chief Medical Director, Veterans Administration.

Monday Afternoon

Presiding: Winchell McK. Craig, Rear Adm., MC, USNR (Ret.), Section of Neurological Surgery, Mayo Clinic, Rochester, Minn.

Hormone-Producing Tumors—Roy Hertz, M. D., Chief, Endocrinology Branch, National Cancer Institute, National Institutes of Health.

Replacement Arthroplasty in Military Patients—Lt. Col. Earl W. Brannon, USAF (MC), 3700th U. S. Air Force Hospital, Lackland Air Force Base.

Preliminary Studies on Bovine Embryo Skin Grafts—Lt. A. N. Silvetti, MC, USNR, Naval Medical Research Institute, National Naval Medical Center, and Blair O. Rogers, M. D., Clinical Instructor in Plastic Surgery, New York University College of Medicine.

Experiences with the Adenovirus Vaccines in Navy Recruits (Co-operative studies of the U. S. Navy, the University of Chicago, and the U. S. Public Health Service)—Joseph A. Bell, M. D., Chief, Epidemiology Section, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health.

Tuesday Morning, 13 November

Presiding: Brig. Gen. Stanhope Bayne-Jones, MC, USAR (Ret.), Formerly Technical Director of Research, Office of the Surgeon General, Department of the Army.

Significance of Leptospirosis in Military Medicine—Lt. Col. Leslie C. Murphy, VC, USA, Deputy Director, Division of Veterinary Medicine, Walter Reed Army Institute of Research.

Rapid Extracorporeal Oxygenation of Banked Blood—Capt. William G. Malette, USAF (MC), Resident Surgeon, Denver Veterans Administration Hospital; William B. Summers, M. D., Denver Veterans Administration Hospital; and Ben Eiseman, M. D., Chief of Surgical Service, Denver Veterans Administration Hospital, and Associate Professor of Surgery, University of Colorado School of Medicine.

Military Operations in Radiologically Contaminated Areas—Lt. Col. James B. Hartgering, MC, USA, Director, Division of Physiology and Pharmacology, Walter Reed Army Institute of Research.

Anorganic Bone Chemistry, Anatomy and Biological Reaction—Comdr. Fred L. Losee, DC, USN, Naval Medical Research Institute, National Naval Medical Center, and Lloyd A. Hurley, M. D., Harlan Memorial Hospital, Harlan, Ky.

Late X-Ray Evidence of Spontaneous Reduction of Dislocation of Cervical Intervertebral Discs—Benjamin H. Kesert, Col., USAR, Consultant in Neurology, Veterans Administration Hospital, Hines, Ill.; Associate, Department of Neurology and Psychiatry, Northwestern University Medical School.

X-Ray Cineradiography and Portable X-Ray Units—Adolph T. Krebs, M. D., Head, Radiobiology Department, Army Medical Research Laboratory, Fort Knox, Ky.

Tuesday Afternoon

Presiding: Col. Victor A. Byrnes, USAF (MC), Director of Professional Services, Office of the Surgeon General, Department of the Air Force.

Preservation of Whole Blood by Freezing—Harold F. Meryman, M. D., Department of Internal Medicine, Yale Medical School.

Cold Weather Survival—Maj. Stanley Lutz, Jr., USAF (MC), Assistant Surgeon, Headquarters, 18th Air Force, Donaldson Air Force Base.

Atherosclerosis and Lipid Metabolism—Daniel Steinberg, M. D., Chief, Section on Metabolism, National Heart Institute, National Institutes of Health.

Results of Early Studies on Effects of Sleep Deprivation—David McK. Rioch, M. D., Director, Division of Neuropsychiatry, Walter Reed Army Institute of Research.

A Hearing Evaluation of an Air Force Squadron of Jet Aircraft Maintenance Personnel—Capt. R. G. Hansen, USAF (MSC), Wright Air Development Center, Wright-Patterson Air Force Base.

Wednesday Morning, 14 November

Presiding: William S. Middleton, M. D., Chief Medical Director, Veterans Administration.

Neurological Complications of Spinal Anesthesia—Myron J. Levin, M. D., Clinical Professor of Anesthesia, University of Illinois College of Medicine, Chicago, Ill.; Assistant Chief, Anesthesia Section, Veterans Administration Hospital, Hines, Ill.

Radiation Control Problems Aboard Nuclear Submarines—Lt. Comdr. John H. Ebersole, MC, USN, Medical Officer, U. S. S. *Seawolf* (SSN 575).

Clotting Factor Abnormalities in Chronic Liver Disease—Joseph R. Goodman, Ph. D., Head, Physiological Research Unit, Medical Research Program, Veterans Administration Hospital, Long Beach, Calif.; Research Associate, Department of Biochemistry and Nutrition, University of Southern California Medical School, Los Angeles, Calif.

The Wholesomeness of Irradiated Food and Its Military Implications—Col. Tyron E. Huber, MC, USA, Research and Development Division, Office of the Surgeon General, Department of the Army.

Practical Application of Pulmonary Physiology for Small Hospitals—Maj. Robert B. Stonehill, USAF (MC), Chief of Pulmonary Disease Section, Lackland Air Force Hospital.

Wednesday Afternoon

Presiding: David E. Price, M. D., Assistant Surgeon General, U. S. Public Health Service, Department of Health, Education, and Welfare.

Future Trends in Military Aviation Medicine—Capt. Ashton Graybiel, MC, USN, Director of Research, School of Aviation Medicine, Naval Air Station, Pensacola, Fla.

Experiences in Evacuation of Severely Burned Patients—Lt. Col. Robert D. Pillsbury, MC, USA, Deputy Commander, Surgical Research Unit, Brooke Army Medical Center.

The Effect of Thyroid Ablation Upon Serum Cholesterol and β -Lipoprotein Spectrum—Joseph R. Goodman, Ph. D., Head, Physiological Research Unit, Investigative Medicine Service, Veterans Administration Hospital, Long Beach, Calif.; Research Associate in Biochemistry, University of California Medical School, Los Angeles, Calif.

Nurse Anesthetist Refresher Course—Capt. Richard J. Ward, USAF (MC), 7100th U. S. Air Force Hospital, Wiesbaden, Germany.

Medical Education for National Defense—Col. Sheldon S. Brownston, USAF (MC), Director of Staff, Office of Secretary of Defense (Health and Medical).

The Tranquilizing Drugs—Edward V. Evarts, M. D., Acting Chief, Laboratory of Clinical Sciences, National Institute of Mental Health, National Institutes of Health.

Effects of Microwaves: Current and Proposed Research—Maj. Daniel B. Williams, USAF (MC), School of Aviation Medicine, U. S. Air Force, Randolph Air Force Base.

BLAKISTON'S NEW GOULD MEDICAL DICTIONARY, A modern comprehensive dictionary of the terms used in all branches of medicine and allied sciences, including medical physics and chemistry, dentistry, pharmacy, nursing, veterinary medicine, zoology and botany, as well as medicolegal terms, edited by *Normand L. Hoerr, M. D.*, and *Arthur Osol, Ph. D.*, with the cooperation of an editorial board and 88 contributors. 2d edition. 1,463 pages; 252 illustrations on 45 plates, 129 in color. The Blakiston Division, McGraw-Hill Book Co., Inc., New York, N. Y., 1956. Price \$11.50.

Here is the dictionary that medical writers and editors have been waiting for. Compiled by a distinguished editorial board and 88 eminent and authoritative contributors in specialized fields, this completely revised and enlarged new edition has kept pace with our ever-growing, rapidly changing, current medical and surgical language. Thousands of new entries (some 12,000), changes (8,000), and modernization of spellings and usage are incorporated; and obsolete and unused terms have been deleted. Recognition of usage was a determining factor in selection. With the exception of the tables on diet and veterinary doses, the same helpful tables and lists, some revised, comprise the appendix; the color plates and halftone illustrations remain as in the first edition. A new table on radioactive and other isotopes commonly used in medicine has been added.

Definitions are concise, clear, accurate. Pronunciation is simplified by syllable division and accent and, when necessary, by phonetic respelling. A convenient key to the respellings acts as a helpful, easy guide.

Rapid finding of any term is facilitated by clear italic, roman, and boldface type. When series of subentries follow main entries they have been set in indented columnar form and each item set off in boldface type.

Altogether, the practitioner, student, medical author and editor, and all others concerned with medicine and the allied fields will appreciate this practical, helpful, and discriminating work.—*E. W. MARTIN*

CLINICAL LABORATORY DIAGNOSIS, by *Samuel A. Levinson, M. S., M. D., Ph. D.*, and *Robert P. MacFate, Ch. E., M. S., Ph. D.* 5th edition. 1,246 pages; 244 illustrations and 13 plates, 11 in color. Lea & Febiger, Philadelphia, Pa., 1956. Price \$12.50.

Five years have elapsed since the last edition of this standard and highly regarded text in clinical pathology. It has been revised, enlarged by 100 pages, and brought up to date. However, the number and titles of the chapters are identical with the previous edition.

The entire chapter on hematology has been revised to include current knowledge of hemorrhagic diseases, anemias, and leukemias. Newer knowledge concerning hemoglobin components along with the use of paper electrophoresis in the analysis of these components is presented. The entire section on hematology is particularly well done. The section on chemistry includes new microchemical methods, additional spectrophotometric analyses, and the spectrum analysis of hemoglobin derivatives, as well as a new discussion on electrolyte balance studies. There is an adequate discussion of blood groups, Rh factor, and the Coombs' test, but the section on blood bank procedures is very brief for this extremely important phase of laboratory work. The reader is referred to the standard texts and reference manuals for details of these procedures. The methods for the performance of the Venereal Disease Research Laboratory slide and tube flocculation tests are included in the chapter on immunology and serology. There is even a brief discussion of the *Treponema pallidum* immobilization test. The chapter on bacteriology has been rewritten with the addition of the method for the determination of the antistreptolysin titer of sera and other new technics. Modifications and improvements have been made in the chapters on tropical diseases and histologic technic. The section on legal medicine and toxicology is an excellent review or introduction to this special field. There is an adequate index as well as a table referring the reader to the proper page for important laboratory tests in the common diseases.

The authors have attempted to bring together in a single volume all the many phases of clinical pathology. They have achieved this objective in discussing the most useful methods of laboratory medicine in a systematic, concise manner. The book is well printed with numerous excellent illustrations. It is highly recommended to the medical student, medical technologist, practicing physician, and pathologist as an authoritative text in clinical laboratory methods.

—MILWARD W. BAYLISS, Col., MC, USA

DISEASES OF THE SKIN, by Richard L. Sutton, Jr., A. M., M. D., F. R. S. (Edin.). 11th edition. 1,479 pages; 1,972 illustrations. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$29.50.

The 11th edition of this standard textbook of dermatology is a worthy successor to the previous editions. During the 13 years since this book was last reprinted and emended, many advances have been made in the specialty, and the author has successfully noted and included in this work these additions. The author has been peculiarly successful in adding to the book hundreds of photographs, many more pertinent subjects and improved discussions. This edition is written more as an outline than previous ones, some subjects having been cut considerably, yet have been treated more precisely and informatively than before. The photographs are superb. The author has added the more recent therapeutic advances in pertinent portions of his text. ACTH, cortisone, and hydrocortisone are discussed, and their uses outlined. There

DISEASES OF THE SKIN, by Richard L. Sutton, Jr., A. M., M. D., F. R. S. (Edin.). 11th edition. 1,479 pages; 1,972 illustrations. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$29.50.

The 11th edition of this standard textbook of dermatology is a worthy successor to the previous editions. During the 13 years since this book was last reprinted and emended, many advances have been made in the specialty, and the author has successfully noted and included in this work these additions. The author has been peculiarly successful in adding to the book hundreds of photographs, many more pertinent subjects and improved discussions. This edition is written more as an outline than previous ones, some subjects having been cut considerably, yet have been treated more precisely and informatively than before. The photographs are superb. The author has added the more recent therapeutic advances in pertinent portions of his text. ACTH, cortisone, and hydrocortisone are discussed, and their uses outlined. There

diagnostic, and therapeutic aspects of diseases of the skin. It is a brief, practical, and useful text for the student and practitioner.

The book is well illustrated with both black and white and colored plates, and the printing is excellent. Organization of the subject matter is practical and useful. Particularly helpful to the nonspecialist is the section included in each chapter on those aspects of nursing that are particularly germane to the diseases considered.

The chapter on general therapeutic suggestions will prove to be a most helpful guide to the beginner.

Dr. Tobias again has succeeded in presenting a wide and difficult subject in a concise and readable form, yet complete enough for everyday use. This book is highly recommended for students of medicine and the nonspecialist.—VICTOR R. HIRSCHMANN, Col., MC, USA

WORLD-ATLAS OF EPIDEMIC DISEASES, Part II, Fourth Issue, edited under the Sponsorship of the Heidelberger Akademie der Wissenschaften by Professor Dr. med. Ernst Rodenwaldt, Heidelberg, in Collaboration with Privatdozent Dr. med. habil. Helmut J. Jusatz, Heidelberg. 36 pages; 11 colored maps. Falk-Verlag, Hamburg 1, Germany, 1956. Price 32 Deutsche marks, plus extra charge for postage and packing.

Any attempt, such as this book makes, to portray African diseases in their entirety in so many diversely governed, seminomadic peoples living under such a variety of climatic and social conditions is bound to leave the student with a feeling of uncertainty. However, such comprehensive coverage will certainly serve as a very fine basis for future studies and evaluation of reports from these areas. Plague, leprosy, poliomyelitis, and smallpox are discussed in detail, and the great gaps in information are clearly stated in the text. The maps, as usual with this series, are detailed and contain data oriented as to time and place, but not as clearly as to race. The text clarifies the map presentations, but careful interpretation is required.

In discussing plague, it was noted that the gigantic wave between 1920 and 1930 carried the series of yearly and seasonal waves to a high crest. No explanation for this large wave was attempted, but it may help explain many baffling facts about plague in this and other areas.

Leprosy and its relationship to tuberculosis, diet, poor sanitation, migration, climate, living conditions, and customs are discussed, but no over-all panaceas are proposed. The changing picture of leprosy in Africa since 1900 and the conclusion, attributed to many authorities, that the total incidence is declining may be misleading. This problem is apparently still very great.

There are five fine climatologic maps of Africa that give fairly detailed data on January and July temperatures, total yearly precipitation in the rainy and dry seasons, and a map of thermal sultriness values (range of comfort)—all of which are of great value in considering the ecology of disease.—GOTTLIEB L. ORTH, Col., MC, USA

- A TEXTBOOK OF OPERATIVE DENTISTRY, by William H. O. McGehee, D. D. S., M. D., F. A. C. D., Harry A. True, D. D. S., F. A. C. D., and E. Frank Inskip, D. D. S., F. A. C. D. 4th edition. 720 pages; illustrated. The Blakiston Division, McGraw-Hill Book Co., Inc., New York, N. Y., 1956. Price \$14.

This is the latest edition of a text that has been standard in its field since 1930. It presents the subject as completely as can be expected in one volume. The first two editions were authored by Doctor McGehee alone, he was joined by the named co-authors for the third edition, and the present edition lists 20 other contributors.

This is a thoroughly modern textbook. Narrative and outline forms of presentation are admirably blended to permit the inclusion of much material without increasing the difficulty of productive study. The 423 figures contain many hundreds of individual illustrations, plus figures from earlier editions. The use of new high-speed materials and techniques is presented in a chapter entitled "Accuracy with Speed." In addition to the expected chapters dealing with dental caries, cavity form, cavity preparation, instrumentation, and filling materials, there are chapters discussing such subjects as efficiency in the arrangement of the dental office and the role of the dental assistant in operative dentistry. Endodontics is presented in a separate chapter, and there is a 93-page chapter on operative dentistry for children, authored by Charles A. Sweet, Sr., and I. Irwin Beechen. As in earlier editions, the importance of adequate diagnosis as a requisite to adequate restorative dentistry is stressed.

The material is both well organized and comprehensively treated; subjects are readily discoverable in the index, easily located in the text, and clearly and concisely presented. This volume can be recommended to both students and practicing dentists.

—JAMES E. CHIPPS, Lt. Col., DC, USA

NEW AND NONOFFICIAL REMEDIES 1956, Containing Descriptions of Drugs Evaluated by the Council on Pharmacy and Chemistry of the American Medical Association. An Annual Publication Issued Under the Direction and Supervision of the Council. 540 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$3.35.

This annual publication of the Council on Pharmacy and Chemistry of the American Medical Association describes drugs, arranged according to their pharmacologic action or clinical use, that have been evaluated by the Council but have not been included in the *Pharmacopeia of the United States*, *The National Formulary*, or, for a prior cumulative 20-year period, in previous *New and Nonofficial Remedies* (NNR). The scope of the book was expanded this year to include not only established useful drugs but also information on all available new drugs. As a result 60 monographs on new drugs were added this year, while only seven from last year's NNR were omitted.

Drugs are described under nonproprietary titles with their chemical or biologic identity, including their actions, uses, side effects, to

city, dosage, and routes of administration. Names of commercial preparations are listed after each monograph.

The general index at the end of the book lists the drugs by their commercial as well as their nonproprietary names.

This volume serves the purpose for which published: to give pertinent and reliable information on new and nonofficial remedies and thereby to encourage rational therapy.—PATRICK I. McSHANE, Col., MC, USA

TEXTBOOK OF MEDICAL PHYSIOLOGY, by Arthur C. Guyton, M. D. 1,030 pages; illustrated. W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$13.50.

This textbook is written primarily for students and is not a reference work. The author's stated intent is to present the philosophy and logic of the mass of knowledge needed by the physiologist and physician. He has accomplished this goal for the medical student by blending enough anatomy and pathology to stimulate the student's interest in the practical aspects of physiology. However, for the physiology student there is too little emphasis on basic mechanisms and the underlying biophysical principles involved. There is only an occasional use of mathematical models, which in many cases can cleverly and simply define a complicated process.

The book consists of 11 major subdivisions and 75 chapters. The subdivisions follow classical lines, i. e., respiration, neurophysiology, circulation, et cetera. The physiologic aspects of aviation, deep-sea diving, and nuclear radiation are covered in special sections but are very brief. There are several misstatements in a short discussion of the "effects of the atom bomb blast on the body."

At the end of each topic a carefully selected bibliography is included. These references were selected for their own broad bibliographies as well as for their individual value and are exceedingly helpful.

In spite of the above limitations, this is a very readable book which will provide anyone interested in human biology with a readily understandable general review.—JAMES B. HARTGERING, Lt. Col., MC, USA

YEAR BOOK OF DERMATOLOGY AND SYPHILOLOGY (1955-1956 Series), by Rudolf L. Baer, M. D., and Victor H. Witten, M. D. 480 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1956. Price \$6.50.

This yearbook contains nearly 400 abstracts of articles received by the editors from December 1954 through November 1955. It has the same format and table of contents as previous editions and has an original article by the authors on therapy with superficial x-rays and Grenz rays. Many foreign articles are abstracted. Some abstracts are rather long and could be shortened to make room for summaries of additional articles. The editors emphasize the current studies on cutaneous enzymes and lipid metabolism, and new information is presented on the relationship of skin diseases and systemic involvement.

Acanthosis nigricans, *incontinentia pigmenti*, and *acrodermatitis atrophicans* are currently receiving much attention. *Psoriasis*, the ubiquitous enigma, is at long last receiving much therapeutic and biochemical investigation.

The abstracts on therapy are useful. Of interest are those on the use of ACTH, cortisone, and hydrocortisone. Various forms of radiation therapy for dermatoses are presented. The forms of radiation such as high-energy electrons and soft radiation from beryllium window tubes may prove of particular value, being highly effective on skin lesions and having little effect on the underlying tissues.

Dermatology needs a good cumulative index. Until one is produced, however, the yearbooks will provide a good working basis for the researcher as well as a general review source.

—WILLIAM N. NEW, *Capt., MC, USN*

OF WATER, SALT AND LIFE, an atlas of 36 pages illustrating 31 color plates, prepared and distributed by Lakeside Laboratories, Inc., Milwaukee, Wis., 1956.

This little book is a beautifully illustrated atlas of fluid and electrolyte balance in health and disease. It consists of 31 colored plates opposite short descriptions of such topics as acid-base balance, pharmacology of diuresis, congestive heart failure, cirrhosis, nephrosis, et cetera. Although some figures require a certain amount of concentration the book does present the feeling of dynamic processes. It should prove to be a valuable aid both to students and to practitioners who may deal with "water, salt, and life."—S. O. WAIFE, *Lt. Comdr., MC, USNR*

DISEASES OF THE ENDOCRINE GLANDS, by Louis J. Soffer, M. D., with J. Lester Gabilove, M. D., and the Section on Gonads by Arthur R. Sobval, M. D. 2d edition. 1,032 pages; 102 illustrations and 3 plates in color; 28 tables. Lea & Febiger, Philadelphia, Pa., 1956. Price \$16.50.

The author discusses the diseases of endocrine glands in separate sections for each gland or, in a few cases, two glands. Reviews of anatomy, embryology, and physiology, which precede the clinical descriptions in each section, contain the details essential for complete understanding of clinically recognizable disease. The chapter on carbohydrate metabolism and diabetes mellitus, included in the first edition, has been excluded from this edition.

Many case reports are advantageously used to amplify the author's descriptions of diseases. The illustrations are clear and adequate, except for a paucity of pictures of patients. Greater use of structural chemical formulas and of tables to bring out similarities of, and differences between, various products of one endocrine gland could add to the value of future editions.

The clarity of presentation makes for easy reading and understanding. The author has, indeed, struck an excellent balance between space allotted to theory and to practice. The endocrinologist interested in the

historical development of our knowledge is unlikely to turn to this book, which is, however, excellently suited to the needs of other physicians.

Because the book is truly up to date in most respects, it was disappointing to read only of the intramuscular corticotropin-eosinophil test for adrenal cortical insufficiency in the section on Addison's disease. Reference is made to Thorn's work, published in 1948. In the appendix, tests using intravenous and intramuscular injection of ACTH are described. However, even there the limitations of the intramuscular injection technic are not discussed.

The appendix (which is devoted to laboratory tests of endocrine function) should be useful to most readers. It could be improved by clarifying the arrangement of order of the tests, perhaps by the use of a preliminary outline or by the use of headings.

In summary, this book can be recommended to general practitioners, internists, and specialists other than endocrinologists as a volume which combines discussions of physiology and disease, theory and practice, and clinical and laboratory aspects in optimum proportions.

—ROBERT J. HOAGLAND, Col., MC, USA

ADVANCES IN VETERINARY SCIENCE, Volume II, edited by C. A. Brandly and E. L. Jungherr. 449 pages; illustrated. Academic Press, Inc., Publishers, New York, N. Y., 1955. Price \$10.

This volume continues the approach made in 1953 in Volume I directed toward the periodic review of progress in the more active fields of research pertinent to veterinary medical science. The editors have had the benefit of a distinguished advisory board in the review and editing of the 11 individual contributions comprising the volume.

The subjects discussed are epizootiology of virus diseases, mycoses in animals, respiratory diseases of poultry, the blood groups of animals, disease caused by deficiencies of trace elements, photosensitization in animals, rumen dysfunction, bovine ketosis, tickborne rickettsioses in South Africa, vibriosis, and effective control of internal parasites.

Each subject is followed by a bibliography. The value of this work is further enhanced by complete author and subject indexes at the back of the volume.

The reviewer inevitably finds himself more interested in some of the areas concerned than in others. Likewise, the differences in approach by the several contributors are pronounced. These range from almost pedantic undergraduate-level abstracts of the literature to extraordinarily thought-provoking interpretations and estimations of the significance of the newly uncovered findings of veterinary and medical research.

The reviewer has seldom encountered a more fascinating and stimulating paper than the contributions on the epizootiology of virus diseases by R. E. Shope. This alone is sufficient to merit the inclusion

of the volume in the libraries of all interested in infectious disease and in veterinary medicine.

In like manner, the discussion of the blood groups of animals by L. C. Ferguson not only merits careful reading but further serves as a ready reference for valuable technics and methodology.

The editors, the advisory board, and the individual contributors have admirably met their objective of producing a volume "of greatest use to the serious student, the research worker, and the practitioner (of veterinary medicine)." This volume should be required reading for all veterinarians of the armed services.

—WILLIAM S. GOCHENOUR, Jr., Lt. Col., VC, USA

CAUSAL FACTORS IN CANCER OF THE LUNG, by Carl V. Weller, M. S., M. D. American Lecture Series, Publication No. 277, A Monograph in American Lectures in Chest Diseases, edited by J. Arthur Myers, M. D., Ph. D. 113 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$3.

Regardless of the time available, it is the dream of every lecturer to be permitted an additional 15 minutes to devote to his subject. The Charles C Thomas Company has done just this in a number of monographs called the "American Lecture Series." Outstanding authorities have been allowed to revise, expand, and annotate their most popular lectures. These have been published and, despite the variety of subjects and of authors, have generally maintained a very high quality. Strangely, the publishers "do not have a completely up-to-date list of The American Lecture Series." To the reviewer this seems a pity. Those volumes of the series which he has examined in the past have been worth owning.

The present volume is typical of this series. The lecture has been expanded to a monograph, supplemented by 121 carefully and well-chosen references. Following a discussion of general considerations, Dr. Weller develops in detail a first theme describing bronchogenic carcinoma as an endemic occupational disease in miners, a second theme describing the search for causes of cancer of the lung in the 20th century, and a third theme concerned with the relation between tobacco smoking and bronchogenic carcinoma.

Although the subject of the lecture is sharply limited, the material is presented in an interesting and even exciting manner. The author has accomplished his objective, which was to explore the "causes, intrinsic and extrinsic, proved and suspected, of bronchogenic cancer." The type and engravings are of high quality, the binding is leatherette, and the volume is handsome in appearance. It is recommended as a valuable addition in any general library and to physicians and workers with a special interest in this field. For those who may have to lecture on this subject, this monograph would be of considerable value.

—ARTHUR STEER, Lt. Col., MC, USA

CURRENT THERAPY, 1956, Latest Approved Methods of Treatment for the Practicing Physician, edited by *Howard F. Conn, M. D.* and 12 consulting editors. 632 pages. W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$11.

This is the eighth edition of this compendium of therapy which fortunately has resisted the expansion in bulk which usually occurs with medical books from edition to edition. The contributors are selected from recognized authorities who are especially interested in the specific disease discussed. They vary with the edition and consequently new viewpoints are given. The outlines of therapy are brief and practical, and treatment methods found useful in the past are not discarded if still effective, although obsolete methods of treatment are omitted.

There is a multitude of new drugs available and those well tried are included; experimental drugs are not included, and note is made when treatment methods not fully tested are given.

At times two different methods of approaching treatment are noted, either of which might be followed successfully or from which the reader might evolve a third of his own, proving that medicine as an art is not yet dead.

This book is a useful desk reference, brief and to the point, which gives the essentials of therapy of each disease and the most up-to-date methods and drugs, and which prevents one's missing some new aspect of treatment.—*JAMES L. TOBIN, Col., USAF (MC)*

THERAPEUTIC USE OF ARTIFICIAL RADIOISOTOPES, edited by *Paul F. Hahn, Ph. D.* 414 pages; illustrated. John Wiley & Sons, Inc., New York, N. Y., 1956. Price \$10.

This 400-page volume represents a compilation of 29 research men's experience in the use of isotopes over a 20-year period. The editor's choice of authors seems for the most part to reflect his philosophy of being more forthright and willing to take some scientific risks in incurable patients in order to more fully understand the capabilities of these medical tools. He feels irradiation is a therapeutic weapon and is not the panacea to the cancer problem. He proceeds to show the results of thorough scientific research in an inspiring and challenging way.

The order of presentation of chapters is excellent. Prefacing the individual uses of isotopes is a section including a short history of the use of radioisotopes, the problems facing even the most astute scientist in using them, their procurement and safe handling, and their effects on tissue. Within these first chapters is an effective blending of doctors of medicine and doctors of other scientific fields. Chapters 2 and 3 might be disconcerting to the novice in this field, and possibly keep him from finishing the book. Yet the subjects of radiologic physics and dosimetry of internal radioisotopes are concisely presented, and by carefully studying these chapters a wide knowledge can be gained in a short time. The procurement of isotopes has been brought

up to date with the addendum to chapter 4. The work by Hymer L. Friedell and P. R. Salerno as reviewed in chapter 6 presents a challenge to all those working in this broad field. Radiation effect is little enough understood, let alone the effect of multiple types of radiation. These men outline methods of research into the synergistic effect of isotopes used in combination that would be well used by others in studying this most urgent problem. Edwin E. Osgood's chapter on the treatment of leukemias and polycythemia vera with radioactive phosphorus is a splendid review of a method of treating the complete patient. The basic histophysiology upon which this treatment is based has been well investigated by the author, and the complete way in which he outlines his course of therapy is excellent. The work by Osgood, Tivey Seaman, et al. is classical. The next chapter also deals with investigative methods for treatment of chronic leukemias, presenting case histories to highlight questions as to mode of action of radiation, problems faced during treatment, and choice of isotopes in treating this disease state.

Chapter 9 is an excellent review of the use of radioiodine in thyrotoxicosis and a brief note on its use in cardiac disease. Chapter 10, on treatment of thyroid carcinoma, is on clinical selection of patients, methods of use of iodine, dosimetry of radiation within the body, complications, a summary of what the author thinks is reasonable management of treatment, and safeguards for the patients and personnel.

The next seven chapters deal with specific colloids, applicators, and implants of isotopes within or on the body in attempts to ablate or palliate cancerous tumors. These chapters have been written by specialists in each field and represent the most advanced knowledge on these subjects. The last chapter, written by G. H. Fletcher, is a concise summary of this man's thought on the advantages and disadvantages of this method of treatment. The book is invaluable to specialist and general practitioner as a guide and review of what has been done in this field.—*RICHARD E. OGBORN, Maj., MC, USA*

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. *Surgery in World War II. Hand Surgery*, edited by *Sterling Bunnell, M. D.* 447 pages; illustrated. Prepared in the Historical Unit, Army Medical Service, under the direction of Colonel Calvin H. Goddard, MC, AUS. Editor-in-Chief, Colonel John Boyd Coates, Jr., MC, USA; Associate Editor for Hand Surgery, Mary E. McDonald; Assistant Editor, Janie W. Williams. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$3.50.

This volume is both a historical document and a report of a clinically important collective experience in the management of the injured hand. Although the format of *résumés* of experiences in the individual theaters of operation and hand centers results in considerable repetition, the basic principles of hand surgery are so unanimously and emphatically emphasized that their importance cannot be missed.

The book is well illustrated with photographs, sketches, and photographic copies of roentgenograms which are usually well placed to conform with the text. Many of the illustrations, however, are so reduced in size that their value is lost—this is particularly true of the roentgenograms.

The influence of the editor, as one of the pioneers in the field of hand surgery and as Civilian Consultant for Hand Surgery to the Secretary of War, is felt throughout the book. Chapter 2—consisting of his conclusions based on his experiences as consultant—is a highly concentrated digest of the principles and details of management of the injured hand, but as such might better have been placed at the end so that he could have commented on some of the differences in approach or viewpoint of the various contributors.

Many important lessons can be learned from this book. It is apparent that hand surgery is an important part of any mass casualty situation and that proper care of the injured hand begins in the field. The need for specialized centers staffed by trained and interested personnel is stressed. This is particularly true in the reconstructive phase of hand surgery.

This book is an important contribution to the field of the surgery of trauma. Based on a wide experience, it is a source of general and specific information on all phases of the management of the injured hand. It should be an invaluable addition to the library of the military and industrial surgeon.—HASKELL M. WERTHEIMER, *Comdr., MC, USN*

EPITOME of the Pharmacopoeia of the United States and the National Formulary with Comments. Issued under the Direction and Supervision of the Council on Pharmacy and Chemistry of the *American Medical Association*. 10th edition. 322 pages. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$3.

For the benefit of those not familiar with this volume, it is designed to follow the material published in the *Pharmacopoeia of the United States* and the *National Formulary*, but to present it in such a form that it will be more valuable to physicians. The two volumes mentioned provide the standards for drugs and drug preparations; however, they also contain much detail that is of value to the pharmacist or drug manufacturer but is of little interest to physicians.

The present edition, of convenient size as to make its ready reference inviting, contains only the essential definitions and descriptions of the drugs listed, with more detail as to the nature of the remedies, their uses and doses. Adverse comment is made on preparations believed to be of doubtful value; however, the wisdom of this is questioned in view of the great deliberation which goes into the acceptance of drugs for the official volumes.

The items are arranged alphabetically by their English names, the uses of which are of particular interest to the prescribing physician,

as is the information relative to market preparations in which the drugs may be found.

Some of the words of caution found in the official volumes are omitted from this volume. This point is of little importance in those cases where the "caution" was directed at the manufacturer or the dispenser. However, in those cases where the words of caution were of prime importance to the physician prescribing the medicines, their omission could possibly have a disastrous effect.

The reference tables are a handy aid, and the organization is well planned. The volume should prove to be a valuable adjunct to the physician's desk or library.—ELWOOD M. WRIGHT, Col., MSC, USA

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. *Vascular Surgery in World War II*, edited by Daniel C. Elkin, M. D., and Michael E. DeBakey, M. D. 465 pages; illustrated. Prepared in the Historical Unit, Army Medical Service, under the direction of Colonel Calvin H. Goddard, MC, AUS. Editor-in-Chief, Colonel John Boyd Coates, Jr., MC, USA. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$4.25.

This volume of the medical history of World War II gives a detailed accounting of complications of traumatic vascular injuries in casualties evacuated to the zone of interior. In this book is statistically recorded what is probably the largest and certainly the most recent and most complete series of vascular injuries to date. Although primarily of historical and statistical nature, the authors have included diagnostic methods, various tests, surgical approaches and techniques as well as valuable pre- and post-operative physiologic data.

The authors tabulate the expected incidence of gangrene which may follow ligation of major vessels. In doing so, Makins' World War I figures on the subject are clarified as is misleading information in the 1943 Military Surgical Manual relative to the expected incidence of gangrene following ligation.

Care of the patient with traumatic aneurysms and arteriovenous fistulas is fully discussed. Additional space is allotted to the systemic effects of arteriovenous fistulas. Statistical data is presented on the results of obliterative operations for these lesions and the value of reparative surgical intervention is stressed. Along with the discussion on surgery is the consideration for sympathectomy. In addition to this excellent study of traumatic aneurysms and arteriovenous fistulas, the incidence, diagnosis, and treatment of patients in World War II with other peripheral vascular disturbances and vasospastic disorders are presented.

Although most of the material in this volume was published in various medical journals prior to this compilation, it is regrettable that this volume was not available for reference at the beginning of the Korean conflict. While this volume is regarded as particularly valuable for

those doing vascular surgery and especially those in the service during hostilities, it is extremely valuable for the use of all general surgeons who may have occasion to treat the complications of acute vascular injuries.—CARL W. HUGHES, Lt. Col., MC, USA

MIGRAINE AND PERIODIC HEADACHE, A Modern Approach to Successful Treatment, by *Nevil Leyton, M. A. (Cantab.)*. 2d edition, reprinted. 122 pages. Published by William Heinemann Medical Books, Ltd., London, England, 1954. Distributed by Charles C Thomas, Publisher, Springfield, Ill. Price \$2.50.

This small, 122-page textbook on headache is as fascinating to the reader as a work of fiction. However, it encompasses the leading scientific theories on etiologic mechanisms of headache and includes some concepts new to this reviewer. Detailed points in the history and physical examination are listed on the differential diagnosis. In addition, a relatively simple method of tackling the migraine problem is presented. This is long-term treatment with the aim of preventing headaches, lengthening the interval between them, or ameliorating the attacks. In fact, the most commonly prescribed relief remedies are barely mentioned.

The author is certain that there are two factors present in the production of migraine: first, an organic diathesis which enables a second, sensitizing factor to produce the alteration of arterial calibre that causes the intracranial pain. A "trigger mechanism" is necessary to set off the sensitizing factor. This latter may be an overproduction of histamine, the cyclic swing of the estrogenic hormones, or the activation by weather, strain, or chronic disease of a neuralgic syndrome. The "trigger" may be psychologic upset, worry, or fatigue.

Treatment is individualistic and includes the progressive injections of an anterior-pituitary-like hormone, histamine injections, the oral use of prostigmine in progressive courses, and the parenteral administration of Vitamin B₁₂ as well as the use of several other less effective drugs.

Nineteen selective case histories are presented and discussed to illustrate various types of headaches and responses to therapy. Economic and social considerations are presented. The book has a summary of conclusions and a good bibliography, and is well indexed. Illustrations consist only of tables and schedules of treatment.

This book is highly recommended to all physicians who see and fret with many patients with headaches. It gives a positive approach toward treatment and an optimistic outlook for doctor and patient alike. I cannot evaluate or corroborate the results of treatment by these methods, as there has been only sufficient time since receiving this book to start a few patients on some of the therapies recommended. If others can give relief to 75 per cent of migraine patients as the author does, or even to a smaller percentage, this book will be a most useful reference in managing these recurring minor tragedies of everyday practice.

—HORACE C. GIBSON, Col., MC, USA

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. Preventive Medicine in World War II. Volume II: Environmental Hygiene. 404 pages; illustrated. Prepared in the Historical Unit, Army Medical Service. Editor-in-Chief, Colonel John Boyd Coates, Jr., MC. Editor for Preventive Medicine, Ebbe Curtis Hoff, Ph. D., M. D. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$3.50.

This volume is one of a series on preventive medicine in the U. S. Army during World War II and records those plans, operations, and activities which modified or controlled the environment for health purposes. The authors have selected from the mass of data available to them those events which highlight the general principles of environmental hygiene and their application under the varying conditions of global warfare. The areas of environmental hygiene covered in this review include: food management, housing, water purification, waste disposal, insect and rodent control, and foreign quarantine. In addition, this volume contains an excellent résumé of the major research developments in preventive medicine during the war, as well as a discussion of the many health problems encountered at the various ports of embarkation.

The result is a concise, well-organized treatise on environmental hygiene as it pertains to a military population during mobilization. It gives the reader a comprehension of the effort, planning, and staffing required of the Medical Department in the successful execution of its mission.

Highly recommended reading for all officers, medical or line, whose present or future responsibilities require a broad knowledge of the means by which military populations are maintained in a state of healthful equilibrium with their environment, it is also recommended for public health officers, graduate students of preventive medicine, civil defense officers, and anyone whose needs require an excellent reference of this type. —HARVEY G. TOUSIGNANT, Lt. Col., USAF (MC)

LAUGHTER AND THE SENSE OF HUMOR, by Edmund Bergler, M. D. 297 pages. Intercontinental Medical Book Corp., New York, N. Y., 1956, in cooperation with Grune & Stratton, Inc., New York, N. Y. Price \$5.

The essence of this entertaining psychoanalytic book is described in the foreword: "The present volume attempts to bring the analytic theory on laughter and wit up to date This book proposes to show that laughter is a necessary and healthy *internal* debunking process and, therefore, a fear-reducing process"

Liberal sprinkled with jokes, bright sayings, and witticisms, the book covers the many theories of humor, and the author presents his own interpretation clearly and forcibly. Although some familiarity with psychiatric concepts (superego, psychic masochism, et cetera) is helpful in appreciating the various points of view expressed, even the non-psychiatrist can find much of interest in this book.

—S. O. WAIFE, Lt. Comdr., MC, USNR

THORACIC SURGERY FOR PHYSIOTHERAPISTS, by Gladys M. Storey, S. R. N., F. C. S. P., with a foreword by N. R. Barrett, M. Chir., F. R. C. S. 132 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$3.

The author of this book provides valuable insights for the student and practicing physical therapist into the conditions which they will encounter and treat in their work. It is a book of basic principles rather than an extensive and detailed study. It offers an understanding of conditions in thoracic surgery which should promote the use of more efficient treatment procedures.

The scope of thoracic surgery has expanded in recent years and now includes the management of many conditions for which, formerly, nothing curative could be attempted. Information on these new techniques and procedures will be found in this book. There is discussion of pulmonary, pleural, cardiac, vascular, pericardial, mediastinal, esophageal, and neurologic conditions.—AGNES P. SNYDER, Lt. Col., AMSC (PT)

TUMORS OF THE SKIN, by Herbert Conway, M. S., M. B., M. D., F. A. C. S. A Monograph in The Bannerstone Division of American Lectures in Surgery, edited by Michael E. DeBakey, M. D., and R. Glen Spurling, M. D. Plastic Surgery Division, edited by James Barrett Brown, M. D. 267 pages; 178 figures; 3 plates in color. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$13.50.

This monograph is divided into two major sections. The first concerns benign tumors of the skin and the second the malignant tumors of the skin.

Each type of tumor is briefly presented. The discussion is chiefly concerned with clinical characteristics and physical findings, frequency of occurrence, treatment, and follow-up data. Following the discussion of each of the various tumors there is a short bibliography with references as recent as 1954.

Surgical treatment of tumors of the skin is emphasized and there is no attempt made to discuss extensively radiation techniques or other nonsurgical methods of treatment. The book is profusely illustrated with photographs of patients with tumors before and after therapy and with artists' sketches of particular operative techniques. However, the book is not a textbook of surgery. The operative techniques illustrated and discussed are to a large extent detailed to emphasize the application of surgical methods in the removal of skin tumors in locations formerly considered beyond the scope of surgical approach and assigned to nonsurgical methods of therapy.

The arrangement of material in this book and the printing makes it easy to read and to use as a ready reference text. The book should be a valuable addition to the library of interns, residents, and advanced surgeons and should also prove interesting to those in other specialties.

—GEORGE F. PEER, Col., MC, USA

New Books Received

Books received by the *U. S. Armed Forces Medical Journal* are acknowledged in this department. Those of greatest interest will be reviewed in a later issue.

- POLYSACCHARIDES IN BIOLOGY**, Transactions of the First Conference, April 27, 28, and 29, 1955, Princeton, N. J., edited by *Georg F. Springer*, M. D. 271 pages; illustrated. Josiah Macy, Jr. Foundation, New York, N. Y., 1956. Price \$5.
- PROPRIOCEPTIVE NEUROMUSCULAR FACILITATION**, Patterns and Techniques, by *Margaret Knott*, B. S., and *Dorothy E. Voss*, B. Ed. Illustrations by *Helen Drew*. Foreword by *Sedgwick Mead*, M. D. 135 pages; illustrated. Paul B. Hoeber, Inc., Medical Book Dept. of Harper & Bros., New York, N. Y., 1956. Price \$5.50.
- CLINICAL ORTHOPAEDICS**, No. 7, "Tumors of Bone." This number contains a special third section on "Motorist Injuries and Motorist Safety" by *Jacob Kulowski*, M. D. *Anthony F. DePalma*, Editor-in-Chief. 354 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$7.50.
- PROCTOLOGY**, by *Harry E. Bacon*, M. D., ScD., LL. D., F. R. S. M. (Lond.), F. A. C. S., F. I. C. S. (Hon.), F. P. C. S. (Hon.), F. J. C. S. (Hon.), F. B. C. S. (Hon.), *Stuart T. Ross*, M. D., F. A. C. S., F. A. P. S., F. I. C. S., and *Porfirio Mayo Recio*, M. D., M. Sc., F. P. C. S., F. I. C. S. 441 pages; 228 illustrations and 5 plates in full color. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$10.
- FUNDAMENTALS OF NURSING**, The Humanities and the Sciences in Nursing, by *Elinor V. Fuerst*, R. N., M. A., and *LuVerne Wolff*, R. N., M. A. 592 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$5.
- PRINCIPLES AND METHODS OF STERILIZATION**, by *John J. Perkins*, M. S. 340 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$8.
- ULCERS OF THE LEGS**, by *Pedro Piulachs*, M. D. 574 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$15.50.
- EMOTIONAL HAZARDS IN ANIMALS AND MAN**, by *Howard S. Liddell*, Ph. D. American Lecture Series, Publication Number 299, A Monograph in American Lectures in Objective Psychiatry, edited by *William Horsley Gantt*, M. D. 97 pages. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$2.50.
- ESSENTIAL UROLOGY**, by *Fletcher H. Colby*, M. D. 3d edition. 656 pages; illustrated. Williams & Wilkins Co., Baltimore, Md., 1956. Price \$8.
- DERMATOLOGY**, by *Donald M. Pillsbury*, M. A., D. Sc. (Hon.), M. D.; *Walter B. Shelley*, M. D., Ph. D.; and *Albert M. Kligman*, M. D., Ph. D. 1,330 pages; 1,117 illustrations on 564 figures. W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$20.
- A GUIDE FOR PSYCHIATRIC AIDES**, by *Charlotte R. Rodeman*, R. N., B. S., M. Ed. 234 pages. The Macmillan Co., New York, N. Y., 1956.

- PRACTITIONERS' CONFERENCES**, Held at the New York Hospital-Cornell Medical Center. Volume 4, edited by *Claude E. Forkner*, M. D. 407 pages; illustrated. Appleton-Century-Crofts, Inc., New York, N. Y., 1956.
- ROENTGEN SIGNS IN CLINICAL DIAGNOSIS**, by *Isadore Meschan*, M. A., M. D., with the assistance of *R. M. F. Farrer-Meschan*, M. B., B. S. 1,058 pages; 2,216 illustrations on 780 figures. W. B. Saunders Co., Philadelphia, Pa., 1956.
- SURGERY FOR GENERAL PRACTICE**, by *Victor Richards*, M. D. 947 pages; 476 illustrations. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$17.50.

Monthly Message

In the February 1, 1956 number of the *Canadian Medical Association Journal* there is a thoughtful editorial on "The Integration of Medical Research." I should like to quote its first paragraph:

Like Humpty Dumpty, medicine has undergone considerable fragmentation; many are in agreement that the time has come to attempt to put the pieces together again, but, as in the case of Humpty Dumpty, the task is proving extremely difficult. There is a steady movement still continuing towards increasing the sub-division of medical science into sub-specialties; there is also an increasingly strong movement towards a cross-fertilization of one discipline by others. It is as yet impossible to forecast the eventual outcome of these two processes but there is no doubting the grave concern which exists at the ignorance of so many sub-specialists regarding work in other fields.

Unfortunately the splintering of medicine into smaller and smaller subspecialties continues. This may be all very well but I should like to recall the well-known epigram that the expert or specialist is one who knows more and more about less and less. The true specialist is one who considers the patient as a whole in addition to whatever "special" pathological condition he has. Therefore the last sentence in the above paragraph is particularly worthy of consideration.

ETIOLOGIC ASPECTS OF ATHEROSCLEROSIS

HORACE C. GIBSON, *Colonel, MC, USA*

THERE is today a vast mass of theory, clinical experience, and investigative data dealing with atherosclerosis. There have been many opposing views, and data have been interpreted differently. I shall try to discuss briefly the more pertinent phases of the problem.

Atherosclerosis is civilized man's greatest killer. Although it has been demonstrated literally from the "cradle to the grave," it takes its greatest toll during middle age—broadly, in men from 40 to 60 years of age and in women from 50 to 70. There is no method of ante-mortem diagnosis before near-total or total closure of an artery, usually a coronary. The emphasis in research is on finding some reliable laboratory methods to tell us which individual is imminently prone to a major catastrophe resulting from the rapid development of atherosclerosis. This goal has not been reached, and, what is more disheartening, the development of successful treatment appears to be as slow and as fraught with pitfalls as methods of diagnosis. Advances, however, are being made in both diagnosis and treatment.

The fine work of Gofman and associates¹ on the mechanism of atherosclerosis, presented in 1950, was of such importance that the United States Public Health Service organized a controlled study of the problem. Page² describes how four laboratories—Berkeley (Gofman and Jones), Pittsburg (Laufer, Hanig, and Barach), Boston (Stare and Mann), and Cleveland (Lewis and Page)—were designated, and work started in the winter of 1950. More than a year was required before the centrifuge analyses and cholesterol measurements agreed sufficiently among these labor-

From U. S. Army Hospital, Fort Jackson, S. C.

Foreword

The *United States Armed Forces Medical Journal* is the medium for disseminating information of administrative and professional interest to all medical personnel of the Department of Defense. The Assistant Secretary of Defense (Health and Medical) and the Surgeons General of the several services invite all medical officers, dental officers, Medical Service Corps officers, Nurse Corps officers, and officers of the Veterinary Corps of the Armed Forces, and the medical consultants of the Army, Navy, and Air Force to submit manuscripts for publication in this *Journal*.

Assistant Secretary of Defense (Health and Medical).

MAJOR GENERAL SILAS B. HAYS,
Surgeon General, United States Army.

REAR ADMIRAL BARTHOLOMEW W. HOGAN,
Surgeon General, United States Navy.

MAJOR GENERAL DAN C. OGLE,
Surgeon General, United States Air Force.

Neither cholesterol nor the other lipids, phospholipid and neutral fat, exist in plasma as pure substances. Lipids are the only large class of vital substances insoluble in water. They are bound to protein in the form of complex lipoprotein molecules. These compounds of lipoproteins contain different proportions of cholesterol, phospholipid, triglycerides, and protein. Electrophoretic or chemical technics separate them grossly into alpha and beta lipoproteins. Ultracentrifugal analysis results in a classification of high- and low-density lipoproteins of varying S_f .

The low-density lipoproteins are considered to be the beta lipoproteins of chemical analysis, and abnormally high values of these are found in clinical heart disease. The high-density, smaller lipoproteins are considered to be alpha lipoproteins, although the precise relationship has not been clarified.³ Lipoproteins serve as important vehicles for lipids, certain vitamins, and probably hormones.³

The average laboratory can determine a total serum cholesterol: This is of significant help if done on a fasting specimen. Although this tells us nothing of the low-density or beta lipoprotein levels, there is fair correlation of high cholesterol levels in atherosclerosis, the usual cause of coronary heart disease. The more elaborate methods of study are extremely expensive. The electrically driven analytic ultracentrifuge which uses an optical and photographic system costs about \$18,000. The maintenance costs on it are very great, and its operation requires a full-time technical staff of two persons. Some attempts have been made to get more accurate results in the separation of the lipoproteins fractions by using the differential preparative machine for separating out the various density lipids, and then running phospholipid, cholesterol, and neutral fat determinations on each of these fractions as well as on the whole serum. There is a prodigious amount of work to be done experimentally before any possible short cuts can be developed. The machine in this case costs only \$5,000.⁴

The hyperlipemia of nephrosis as well as of some other diseases is dependent on a metabolic disorder which involves protein as well as lipid. Page suggests that a defect in the synthesis or degradation of the protein moiety of the lipoproteins might be at fault, and that this possible defective protein metabolism may be as important as defective lipid metabolism in atherogenesis.

"FILTRATION" THEORY

The arteries are respiring, pulsating musculofibrous tubes. The arterial tissue uses oxygen and nourishment and is supplied by vasa vasorum—numerous small arteries distributed to the outer fibrous and elastic layer (tunica externa) and to the tunica media, the muscular layer. The blood is returned by small venae vasorum from the same layers. The inner layer, or tunica intima,

atories. Next, the serum of 12,000 normal people was studied, and each year since a follow-up has been made to determine whether myocardial infarction or other evident vascular disease has developed. These data are now undergoing statistical treatment in Washington. The first results are expected to be published sometime this year.²

In essence, Gofman's working hypothesis of lipoprotein interconversions is that a certain class of lipoproteins, *i. e.*, those with serum flotation (S_f) rates between 12 and 20 Svedberg units, are atherogenic. In humans, molecules in the S_f 12-20 class were found to contain about 30 per cent cholesterol and little protein. The quantitative presence of these molecules was statistically related to atherogenesis. Later a second class of molecules was added as significant in atherogenesis, namely, the S_f 20-100, and still later another class, S_f 100-400, less significant in atherogenesis and which may be greatly elevated by a fat meal. Lipid may enter this system in the form of high S_f lipoproteins, and as these complexes yield their neutral fat to the body depots, high S_f lipoproteins are successively changed to lower S_f members of the series.³ Are these restricted classes of serum lipoproteins, when they are in high quantity in the circulating blood, the ones which signal developing atheroma? As yet there is no clear answer, but the trend among most authorities is toward accepting this concept. However, until the conclusions of the joint laboratory study are known, Gofman's concepts must be considered neither confirmed nor denied.

Goldbloom and associates⁴ recently reported on the study of 500 subjects aged 13 to 100 years and found that at the ages of 60 to 75 years the trend toward increase of total lipids, certain serum lipoproteins, the atherogenic index, and the incidence of aortic dilatation is reversed. All these values begin to decline due to some invisible, not-understood barrier. Normal persons thus acquire their "second youth," and this may explain why they attain such ages as 80 to 100 years. On the other hand, perhaps those who do had throughout life a favorable chemical balance of their androgen and estrogen production.

NATURE OF INVOLVED LIPIDS AND PROTEINS

Absorption of cholesterol from the intestinal tract is by lymphatics along with fats and the necessary bile. Cholesterol esterified with fatty acids constitutes about 70 per cent of plasma cholesterol and is the more stable form of cholesterol. The liver appears to be necessary for conversion of the free to the ester form. Most tissues, except brain, can synthesize cholesterol, but the liver is most active in this regard, and the evidence points to the control of the plasma cholesterol by the liver.⁵

Neither cholesterol nor the other lipids, phospholipid and neutral fat, exist in plasma as pure substances. Lipids are the only large class of vital substances insoluble in water. They are bound to protein in the form of complex lipoprotein molecules. These compounds of lipoproteins contain different proportions of cholesterol, phospholipid, triglycerides, and protein. Electrophoretic or chemical technics separate them grossly into alpha and beta lipoproteins. Ultracentrifugal analysis results in a classification of high- and low-density lipoproteins of varying S_f .

The low-density lipoproteins are considered to be the beta lipoproteins of chemical analysis, and abnormally high values of these are found in clinical heart disease. The high-density, smaller lipoproteins are considered to be alpha lipoproteins, although the precise relationship has not been clarified.⁴ Lipoproteins serve as important vehicles for lipids, certain vitamins, and probably hormones.⁵

The average laboratory can determine a total serum cholesterol. This is of significant help if done on a fasting specimen. Although this tells us nothing of the low-density or beta lipoprotein levels, there is fair correlation of high cholesterol levels in atherosclerosis, the usual cause of coronary heart disease. The more elaborate methods of study are extremely expensive. The electrically driven analytic ultracentrifuge which uses an optical and photographic system costs about \$18,000. The maintenance costs on it are very great, and its operation requires a full-time technical staff of two persons. Some attempts have been made to get more accurate results in the separation of the lipoproteins fractions by using the differential preparative machine for separating out the various density lipids, and then running phospholipid, cholesterol, and neutral fat determinations on each of these fractions as well as on the whole serum. There is a prodigious amount of work to be done experimentally before any possible short cuts can be developed. The machine in this case costs only \$5,000.⁶

The hyperlipemia of nephrosis as well as of some other diseases is dependent on a metabolic disorder which involves protein as well as lipid. Page suggests that a defect in the synthesis or degradation of the protein moiety of the lipoproteins might be at fault, and that this possible defective protein metabolism may be as important as defective lipid metabolism in atherogenesis.

"FILTRATION" THEORY

The arteries are respiring, pulsating musculofibrous tubes. The arterial tissue uses oxygen and nourishment and is supplied by vasa vasorum—numerous small arteries distributed to the outer fibrous and elastic layer (tunica externa) and to the tunica media, the muscular layer. The blood is returned by small venae vasorum from the same layers. The inner layer, or tunica intima,

in arteries of medium size is composed of the endothelial lining, a thin layer of fine areolar tissue fibers and cells called sub-endothelial areolar tissue, and a layer of elastic fibrils running more or less longitudinally, forming an elastic, fenestrated membrano called the elastic lamina.

Apparently the intima has no capillaries running through it. Cleftlike intercellular spaces are present in the intima and media. They may be regarded as the commencement of lymph vessels, but definite lymph vessels are found only in the outer tunic.⁷ The "filtration" concept of atherogenesis subscribed to by Page² and Martt and Connor⁴ and generally accepted is as follows: Lipoprotein molecules filter from the plasma by lateral arterial pressure through the intima and into the media where they are picked up by the capillaries or by the adventitial lymph ducts. Some of these lipoprotein particles got caught in the subendothelial areolar tissue, either because the vessel fails to function properly as a filter or because the size, shape, and charge of the lipoproteins is such as to allow them to stick.

There is clear evidence that subendothelial fibroblastic proliferation, defects in the inner elastic lamella, and changes in the ground substance often are quite as impressive and may even precede the lipid changes of atherosclerosis. Changes in the arrangement, amount, and chemical nature of subendothelial ground substance may alter the filter function. This layer becomes thicker with long stress of hypertension. The nature of the lipid deposited and the responsiveness of the tissue to it will determine whether the lesion remains quiescent or whether a tissue reaction occurs which may cause necrosis and/or initiate a mural thrombus.³

Histologists tell us that mural thrombi are common in arteries during middle age and later. Most are asymptomatic, are soon covered by endothelium, and incorporated into the intima, gradually fibrosing and becoming additional layers to the atherosclerotic plaques. Segmental arterial spasm around a fresh thrombus may cause complete closure in an otherwise partially open vessel, hence the very great importance of nitrites in the treatment of early coronary occlusion.⁸

In early atherosclerosis the vessel wall shows a slowly progressive increase in total lipid content, of similar composition to plasma. This continues for some time and supports the view that the source of the vessel wall lipid is plasma lipid. The beta lipoprotein is considered to be the chief carrier of unstably held lipid. As the filtered lipoprotein breaks down, this "lightly bound" lipid is shed within the vessel wall. This lipid, freed from its combination with protein, is now insoluble in water, is foreign,

and is the nidus of a foreign-body reaction. As necrosis occurs, the normal plasma constituents, neutral fat, phospholipid, and free cholesterol decrease, and ester cholesterol increases disproportionately.

The basis of this concept accepts the movement of large amounts of plasma constituents through the vessel walls. To review all the work supporting this theory is not within the scope of this article.

HYPERTENSION, OTHER ASSOCIATED DISEASES

When Master's criteria¹⁰ are used, 5 per cent of individuals may be expected to have hypertension. Recently Goldstein and associates¹¹ found that 23.7 per cent of 135 males and 55 per cent of 65 females with coronary occlusion had hypertension. Therefore, hypertension occurred 4.75 times more frequently in their group of males and 11.5 times more frequently in their group of females with coronary occlusion than in otherwise comparable individuals without coronary occlusion. Hypertension is relatively more important in the female. This can be explained on the increased susceptibility of males in the fifth and sixth decades to atherosclerosis with or without hypertension. Premenopausal women are less prone to develop atherosclerosis and coronary occlusion, with or without hypertension. This is presumed to be due to the protective high estrogen production. Castrated women do not manifest this protection.

The concentration of alpha and beta lipoproteins is normal in early essential hypertension. But, as it becomes severe or malignant, the classes of lipoproteins considered by Gofman and associates to be atherogenic all increase. The development of vascular disease, atherosclerotic, and/or hypertensive, especially if there is renal involvement, seems to be associated with great disturbance in the normal lipoprotein pattern of the blood.

Nephrotic, diabetic, and myxedematous patients also show abnormal lipoprotein patterns. These are examples of accelerated atherogenesis, and do not preclude other more slowly progressive varieties in which there is no detectable change in lipoproteins from what we consider normal.²

Idiopathic hyperlipemia is a hereditary condition in which there is a high fasting level of serum neutral fat. The triad of signs and symptoms includes abdominal pain, hepatosplenomegaly, and cutaneous xanthomata. Gofman and associates indicated that these patients have elevations of lipoprotein molecules of the classes S₁ 100-400 which are normally elevated after the ingestion of dietary fat. Clearance tests for orally ingested neutral fat, tagged with radioactive iodine, and vitamin A tolerance tests indicate a striking delay in the clearance of fat from the serum.

The condition is thought to be due to failure of liver and fat depots to remove dietary fat from the blood stream at a normal rate. The cause may, however, be an inherent inability to form adequate amounts of heparin. Restriction of dietary fat, with or without heparin, relieves the symptoms and lowers the plasma lipid much like restriction of carbohydrate, with or without insulin, lowers blood sugar and relieves the symptoms of diabetes mellitus. Hyperlipemic patients are subject to symptoms of coronary insufficiency which are relieved by treatment. Recently Martt and Connor⁴ reported the first autopsied case of coronary occlusion occurring in a patient with idiopathic hyperlipemia.

ENVIRONMENT

Factors of habit and environment as well as inheritance have been blamed as causes of atherosclerosis. I shall dismiss tobacco and alcohol from further discussion as there is insufficient reliable evidence on which to incriminate them in causing atherosclerosis. There is good evidence that tobacco increases established coronary insufficiency, probably by spasm—hence its importance here. And, at the risk of being very unpopular, I must say that reliable work does not bear out the coronary dilating theory of alcohol.⁴ Perhaps we can still be comforted by the thought that, used properly, alcohol relieves some of the anxiety and stress of the day and under its mellowing influence we can have our coronary occlusions with less pain and strain.

Exertion within limits is more beneficial than harmful. The active man metabolizes exogenous dietary cholesterol and fats faster than the sedentary man. Men in sedentary occupations are more likely to develop coronary heart disease and, since this is caused by atherosclerosis, physical inactivity may influence its development or progression. The increased rhythmic expansion and contraction of the arteries during exercise may aid the pickup of lipids filtering through the vessel wall by lymph channels.

Occupation appears to influence atherogenesis, I believe indirectly. Perhaps it is that successful businessmen become successful because they have more drive—a preponderance of androgens over estrogens. Or with the mental stress of recurring minor crises, the effect of increased output of corticoids and intermittent elevations of blood pressure may play a part in atherogenesis. Finally, it may be that their living and eating habits result in an increased intake of fats. The increased incidence of atherosclerosis in middle-aged career soldiers is possibly related to the high content of fat in the Army ration.

The influence of fat in the diet has been considered in most countries of the world as an important factor in atherogenesis. The evidence, briefly, is as follows: In Norway during the war years, 1940 to 1945, during a marked curtailment of fat in the

diet, a sharp reduction in the incidence of deaths from coronary, cerebral, and generalized arteriosclerosis was reported. The reduction was approximately 50 per cent. From England a 50 per cent reduction of mortality in diabetics over the age of 45 is reported since the government instituted the rationing of fat at the onset of the last war. Over 100,000 diabetics in England alone have had their lives saved. Similar reports, though less impressive, come from France, Italy, Sweden, Finland, and Denmark.¹² Scattered reports of series of patients treated in this country by a low-fat diet in general favor the reduction of fat along with an over-all lowering of the caloric intake in the treatment of coronary atherosclerosis.^{6,12,13} My own experience indicates excess fat intake to be one of the environmental factors which accelerates onset and progression of atherosclerosis. This is still controversial, however. Two recent studies not only present additional data reflecting the adverse influence of fats in the diet of patients with coronary occlusion, but they also lend support to the belief that the low-fat diet results in prolonged lowering of blood lipids. In the study by Roen,¹⁴ 82 per cent of the total initial drop in serum cholesterol was maintained in 50 patients. The period of treatment at the time of the report was from 2½ to 4½ years. Unfortunately, ages were not given. The study from the University of California by Lyon and associates¹⁵ was most complete and gave a follow-up study for a 5-year period of 351 patients with myocardial infarction and 119 patients with angina pectoris. In patients who did not adhere to a low-fat, low-cholesterol diet, the recurrence and death rate was 4 times as high as in patients who adhered to the diet. The low-fat, low-cholesterol diet was found to be effective in maintaining chronically lowered lipoprotein atherogenic index values.

Further information concerning the effect of a prolonged low-fat diet in maintaining a prolonged lowering of plasma cholesterol may be obtained from studies on repatriated American prisoners of the Korean conflict. During "Operation Little Switch" I was one of a group in a position to make certain studies which were published.¹⁶ Serum cholesterol was run on 67 consecutive American prisoners within 24 hours of release by the enemy. The average value was 151 mg per 100 ml, including four with high levels compatible with familial hypercholesteremia. These four were in the range of 500 to 600 mg per 100 ml. None of the remaining 63 were above 250 mg per 100 ml. Twenty-four had values below 130 mg per 100 ml. These men had been on low-fat, low-caloric diets for two to three years. The mean value of cholesterol done on serum of 25 nonprisoner soldiers at the same time by the same laboratory* was 219 mg per 100 ml.

*U. S. Army Tokyo General Laboratory

HEREDITY

Administration of methyltestosterone has been shown to alter the lipoproteins of serum in that the alpha levels are reduced and the beta levels are elevated. This is thought to be due to the androgenic influence on hepatic function.

Clinical trials of estrogens in males following coronary occlusion have shown increased protection from second occlusions.¹⁴ The gynecomastia, loss of libido, and impotence were deterring complications in the earlier trials. However, trials with smaller dosages of different estrogens reportedly have resulted in minimizing the unfavorable side effects while retaining the protective action. The essence of a great deal of work with the sex hormones is that testosterone increases the beta lipoproteins. Estrogens are efficacious only insofar as they inhibit testicular androgen production, primarily via pituitary gonadotrophic inhibition and secondarily by neutralizing the circulating androgen. They have no effect in the postmenopausal atherosclerotic female, but are helpful in the premenopausal diabetic female in whom hypo-ovarianism is common. After castration, estrogen functions solely as an adrenal androgen depressant.¹⁵

Eleven relatively young men were currently under treatment for atherosclerotic heart disease in the outpatient facilities of this hospital. Their ages ranged from 32 to 52 years, 5 being under 40. Because of the seriousness of coronary disease in this age group, a trial on estrogen therapy was felt to be justified. A 75-year-old man with carcinoma of the prostate, who had had an orchidectomy, was added for interest. Plasma lipoprotein levels of alpha, beta, S₁ 12-20, and S₁ 20-100 fractions were done at the Walter Reed Army Institute of Research. After the initial determinations, each patient was treated with 0.02 mg of ethinyl estradiol daily for seven weeks. The plasma lipoprotein fractions were again determined, and individual values are shown in table 1. The results were altogether inconclusive. The treatment caused no undesirable symptoms during this period. Estrogen was discontinued. Low-fat, low-cholesterol diets were prescribed for all, and some were started on heparin sodium therapy. After using heparin sodium in a few for familiarization, it is planned to treat most of these men biweekly with 150 to 250 mg of concentrated aqueous heparin sodium subcutaneously for its plasma lipid-clearing action. The laboratory studies will be repeated later at 24- and 48-hour intervals following the previous injection.

Present studies of the cause of atherosclerosis have placed most of the emphasis upon an abnormal elevation of various lipid fractions, the levels of which are affected by patterns of heredity as well as by certain disease states and the increased ingestion of dietary fats. Atherosclerosis, particularly the coronary type, runs in families and represents a mild form of hereditary dis-

turbance of lipid metabolism. Alvord,¹¹ for instance, found that 15 members of one family had hyperlipemia, 6 had xanthoma tuberosum, and 18 had a history suggesting disease of the coronary arteries. A recent survey¹² of a group of Navajo Indians showed albumin to be lower than normal, and alpha and gamma globulin elevated. Alpha and beta lipoproteins were low, but other lipoproteins were normal. Total cholesterol values were considerably lower than what we consider to be normal. Since diet was the same as that given to the non-Indian control group, heredity appeared to be the most likely explanation for the different values found. The Navajos have a low incidence of coronary disease. Idiopathic hypercholesteremia may be produced by a single dominant gene. This could determine an individual's capacities and the nature of his reaction under specific conditions. Causative hereditary and environmental factors co-exist and are by no means mutually exclusive.

Men with the body type of prominent muscularity, compactness, and "maleness," the so-called mesomorphic type, are most likely to develop coronary disease at a younger age. Obviously, mesomorphy is hardly a remediable condition, but it is possible that diet and other measures may prevent the early onset of coronary atherosclerosis in this group.

Certain races appear to be prone to atherosclerosis regardless of diet. The Jews are perhaps the best example of this. Do Jewish males produce more testosterone and/or less heparin than, for example, Eskimos, who on a high-fat diet have a low incidence of atherosclerosis? Or is the anatomy, biochemistry, and physiology of the vessel wall, all of which are hereditarily conditioned, different in different races?

Studies of mast cells, which produce heparin, have shown decreased numbers of these cells in atherosclerosis, along with decreased amounts of circulating heparin. A recent report from the Cedars of Lebanon Hospital, Los Angeles, Calif.,³ may indicate the importance of heparin sodium in the treatment as well as the development of atherosclerosis. One hundred and five patients with known previous myocardial infarctions were given 200 mg of aqueous heparin sodium subcutaneously twice weekly. One hundred and seventeen alternate patients with the same diagnosis and in the same age group were given injections of saline solution. Treatment was given for from 6 to 18 months, and at the end of 2 years there were 21 deaths due to cardiovascular disease in the control group and 4 in the heparin sodium-treated group. Symptomatic improvement occurred in 25 to 35 per cent of the controls and in 50 to 75 per cent of the treated group. These workers found that this dose of heparin sodium significantly lowered the blood level of low-density lipoproteins in these patients for as long as 24 to 36 hours and in some for as long as 72 hours.³

TABLE 1. Blood lipid values in 12 patients with coronary heart disease

Clinical data						Lipoproteins (mg/100 ml) before estrogen therapy				After 7 weeks of 0.02 mg ethinyl estradiol daily			
Patient	Age	Diagnosis	Months since onset	Other diseases	Total cholesterol	Alpha lipoprotein (76-142)*	Beta lipoprotein (61-189)	S _f 12-20 (43-51)	S _f 20-100 (72-84)	Alpha lipoprotein	Beta lipoprotein	S _f 12-20	S _f 20-100

*(): Normal values — : Abnormal values

In all studies of the infiltration of vascular walls by lipids, time is an important factor. Thus, if the injection of heparin sodium is followed by a marked though temporary reduction of the low density lipoproteins, a transformation from high S_1 to lower S_1 lipoproteins, as reported by several workers,^{1,2,20} considerable time may elapse even after the serum lipoproteins have reached their preheparin levels before substantial amounts again penetrate into the arterial walls. Furthermore, macromolecules form films upon the surfaces of the cells and the vascular intima, and, because of their inability to escape through the pores, would be most likely to form fat sludges on the endothelium. Since it is precisely these larger fat particles which almost disappear following an adequate dose of heparin sodium, the harmful effects of intimal films—prevention of normal molecular exchange between the plasma and interstitial fluid, and the accumulation in the subendothelial tissues—should be substantially ameliorated by heparin sodium therapy. Reformation of films should take longer than the reaccumulation of plasma lipoproteins.

Finally, the beta lipoproteins have been found to interfere with glucose uptake in muscle. Their lowered concentration following heparin sodium therapy may permit more normal carbohydrate metabolism in diabetes.⁵ This may be vital to heart muscles barely getting enough blood through a narrowed coronary artery.

Heparin sodium may be valuable in preventing platelet agglutination on the cement substance of injured endothelium, which may be the initial step in thrombosis. This is aside from its general anticoagulant action.

Heparin sodium may be used for years with no greater risk of hematoma formation or bleeding than the diabetic's risk from insulin reactions. In fact, insulin dosage should be lowered if heparin sodium is used in a patient taking insulin, since not as much is required.

A great number of investigators favor the use of heparin sodium as an anticoagulant in the prolonged treatment of impending or acute coronary occlusion because of its greater safety, dependability, and the relatively little laboratory control it requires, as well as for its lipid-clearing action.²¹⁻²³ This latter may prove to be vital, as ultracentrifugal studies have demonstrated that lipemic clearing is the result of a shift of serum lipoproteins from larger to smaller, less harmful particles.²⁴ Of more immediate clinical importance, however, is the recent appreciation that alimentary lipemia is associated with increased coagulability of the blood,²⁵ increased platelet adhesiveness and aggregation of erythrocytes, and an increase in viscosity.²⁶⁻²⁸

SUMMARY AND CONCLUSIONS

The evidence is fairly conclusive that the circulating lipoproteins are the source of the increased lipids found in atherosclerotic vascular walls. The physical state and particle size of the lipoproteins are important, probably due to the filtration properties of the vessel walls.

Studies of numbers of mast cells in animals and humans, and of circulating heparin levels, indicate that decreased heparin production in the body may be etiologically important in the accumulation of large amounts of circulating low-density serum lipoproteins.

An unfavorable chemical balance of androgen over estrogen often results in increased levels of beta lipoproteins, which appears to be the prerequisite to atherogenesis. Treatment of 12 patients with 0.02 mg of ethinyl estradiol daily for seven weeks failed to produce consistent laboratory improvement.

Factors such as hypertension, diabetes mellitus, nephrosis, myxedema, local factors in the vascular wall, race, and eating habits unfavorably influence atherosclerosis.

ACKNOWLEDGMENT: The author wishes to thank Col. W. D. Graham, MC, USA, for co-ordinating the laboratory work required and assisting in the preparation of this article.

PSYCHIATRIC PREDICTION AND MILITARY EFFECTIVENESS

Part II*

ALBERT J. GLASS, *Colonel, MC, USA*

FRANCIS J. RYAN, *Captain, MSC, USA*

ARDIE LUBIN, *Ph. D.*

C. V. RAMANA

ANTHONY C. TUCKER, *Colonel, MSC, USA*

THE FIRST part of this study demonstrated that when psychiatrists estimated the future effectiveness of recruit inductees, their predictions of satisfactory duty were usually correct, but they were unable to efficiently identify the potentially unsatisfactory soldier. However, there still was the possibility that various components of the mental examination may be more accurate indicators of future unsatisfactory service than the over-all impression of the psychiatrist. For example, it was found that parental disharmony in the formative years, a poor school record was highly correlated with inadequate military duty, psychiatric selection could be made more efficient by properly weighing the positive history of such developmental events. In order to test this assumption, separate elements of the psychiatric examination were compared to military effectiveness.**

FAMILY HISTORY AND MILITARY PERFORMANCE

A major portion of the psychiatric examination was devoted to the circumstances of the early formative environment. Included in this sphere was the psychiatric status of parents and siblings as reported by the subjects. Family members were rated as mentally disturbed if there was a history of psychosis, neurosis, or clear-cut personality disorder. Symptoms of a clear-cut personality disorder included alcoholism, seclusiveness, and antisocial behavior. Table 12 indicates a small but significant relationship between psychiatric abnormalities in siblings and

*Part I was published in the October 1956 issue of this Journal.

From Walter Reed Army Institute of Research, Walter Reed Army Medical Center, Washington, D. C.

unsatisfactory military performance. The influence of mental disturbance in the mother is similar but less striking, although still statistically significant. Psychiatric abnormality of the father was unrelated to military effectiveness.

Another component of the family history concerned the absence of one or both parents because of death, divorce, or severe chronic illness. It is reasonable to believe that inductees from so-called "broken homes" are more apt to become marginal or poor soldiers than individuals who originate from "normal" homes. This hypothesis was tested in table 12 with negative results. Similar inconclusive findings were obtained when the influence of substitute parents upon military performance was explored.

Conflict between parents is usually regarded as deleterious to adequate childhood development. However, table 12 reveals that parental disharmony was not related to military effectiveness. Negative results were also obtained when the influence of overt sibling rivalry upon later duty performance was considered.

The psychiatric examination also recorded the attitude of the subjects toward their parents. Most subjects gave conventional responses of normal positive feelings toward father and mother. The small minority who expressed deviant attitudes of over-attachment, resentment, or ambivalence did not exhibit a significant diminution of military function (table 12).

Economic status of the family during the formative years may play a role in the formation of adult patterns of behavior. Parental economic status was rated as marginal or relief only if difficult financial conditions persisted for two or more years. Table 12 demonstrates that this aspect of family history was statistically related to military effectiveness.

It can be postulated that past or current assimilation difficulties of foreign-born subjects or subjects with foreign-born parents may hinder adjustment to the new military environment. In measuring the effect of cultural differences upon ability to function in the Army, table 12 reveals that this apparent handicap was not a barrier to satisfactory duty.

The influence of religion in the home also was explored for its relationship to military effectiveness. A majority of subjects studied stated that religion was a positive force in the childhood home. The remainder reported religion to be of little or no importance in their formative years. As shown in table 12, this aspect of the early environment did not significantly alter military effectiveness.

The position of the individual in the family constellation in relation to other siblings has been cited as pertinent in the

development of personality traits such as aggressiveness, dependency, and the like. This question is considered in table 13, and the results indicate that family position had no significance insofar as military performance was concerned.

TABLE 13. *Position in sibling constellation and military performance**

Position	Number	Per cent satisfactory duty
Youngest, only boy, or only child	230	90
Eldest child or eldest boy	176	88
Middle or other child	99	88

*Level of statistical significance .5

To recapitulate, this study could establish little or no relationship between environmental circumstances of the past as related by the subjects and their military performance. These rather negative results do not negate commonly held beliefs that early experiences influence later adult behavioral patterns. The results do indicate that retrospective and subjective accounts of the past as given by subjects under conditions of psychiatric evaluation in this or similar studies were not valid indicators of military performance. Moreover, although the death of parents, financial hardship, and position in the family are factual, it apparently is the impact of these events upon the individual that is of more significance for later behavior than is their mere occurrence.

PRESERVICE ADJUSTMENT AND MILITARY PERFORMANCE

The second major section of the standardized psychiatric examination dealt with behavior of the subject prior to induction. The first item in this area concerned the individual's adjustment to the family. Adjustment was rated as questionable or impaired if the subject (1) left home before the end of adolescence, (2) quarrelled incessantly with parents or siblings, or (3) was overly dependent upon the family, unable to make independent decisions, et cetera.

Table 14 indicates a small but significant relationship between faulty family adjustment and unsatisfactory military duty.

Another element of preservice behavior involved sexual adjustment. A rating of questionable or impaired adjustment in this sphere was given if there was a history of: (1) repressed sexual drive as manifested by avoidance of the opposite sex, lack of sexual activity, or disgust and overly moral attitudes; (2) exces-

sive preoccupation with sex over an extended period; or (3) persistent overt homosexual desires or activity.

TABLE 14. *Preservice adjustment and military performance*

Area of maladjustment	Satisfactory duty				Statistical significance
	Positive history		Negative history		
	No.	%	No.	%	
Parental family	86	80	419	91	.01
Sex	124	89	381	89	NS*
School	152	80	353	93	.001
Work	71	76	434	91	.001
Social and recreational life	79	80	426	91	.01
Community	36	67	469	91	.001

*No significance

As demonstrated in table 14, inadequate sexual adjustment was not related to military effectiveness. This finding is not surprising since the sexual drive is usually in a state of flux during early adult life. Thus it was difficult to establish valid criteria of sexual normalcy for the young subjects of this study.

Tangible evidence of achievement and conformity in a structured environment is represented by the school record, which should be a good indicator of future military performance. School adjustment was rated as questionable or impaired if there was a history of (1) consistent failure of the subject to apply himself to his academic task; (2) marked failure to associate with fellow students; or (3) serious disciplinary difficulties with teachers.

As expected, this criterion was significantly correlated with military performance (table 14).

The work record is another objective past accomplishment which involves tasks and obligations similar to that imposed by military service. However, most of the youthful subjects in this study had relatively little time in which to establish patterns of work behavior. A rating of questionable or impaired work adjustment was given if there was (1) floating from job to job; (2) repeated discharges from jobs; (3) chronic difficulties with fellow employees or superiors; or (4) failure to work when opportunities are available.

Based on the above criteria, table 14 reveals that the work record, even in young subjects, was significantly related to military effectiveness.

In assessing social and recreational adjustment, the examining psychiatrists were requested to take into account all interpersonal relationships not centered upon home, work, school, or sex. Impairment in this category was considered present if there was evidence of (1) seclusive, withdrawn behavior; (2) overly aggressive or hostile behavior toward others; or (3) absence of any recreational life.

Table 14 indicates that maladjustment in this area was also statistically correlated with military performance.

The last category of preservice behavior concerned adjustment to the community. A rating of maladjustment was given if there had occurred (1) overt crimes of one kind or another; or (2) *trouble-making short of criminal behavior*, such as public brawling, obnoxious behavior, when drunk, et cetera.

Table 14 revealed that antisocial behavior was the most significant preservice indicator of unsatisfactory military duty. Because of past and present induction standards which exclude persons who have been convicted of a felony, there were relatively few subjects who were rated as having impaired community adjustment.

It is apparent from table 14 that preservice adjustment is a more efficient predictor of later military performance than the category of family history. Yet it should not be forgotten that the bulk of subjects who were considered maladjusted in any area of preservice behavior did render satisfactory duty. Therefore a positive history of such deviant behavior can only indicate an increased probability of noneffective military functioning rather than a valid reason for psychiatric rejection.

It was not possible to improve the efficiency of prediction by adding two or more criteria of preservice adjustment. The number of subjects who were rated as maladjusted in several areas were too few for accurate statistical analysis. Also little additive benefits were achieved by combining two or more criteria of impaired preservice behavior since the same phenomenon was measured; namely, maladjustment to the preservice environment as represented by school, work, or the community.

PSYCHOPATHOLOGY AND MILITARY PERFORMANCE

The standard examination form required the psychiatrist to record his clinical impression regarding the extent of psychopathology that was found, in relation to the following categories:

1. Well integrated.

2. *Neurotic personality*—used to designate neurotic traits or immature reactions which did not disable or incapacitate.

3. Suggestive neurosis—for suggestive psychogenic somatization reactions, immature reactions, or long-standing neurotic symptoms, where there is no clear-cut incapacity or illness.

4. Overt neurosis—where incapacity has resulted from neurotic traits or symptoms.

5. Pathologic personality—includes excessive seclusiveness, anti-social behavior, sexual deviations, and definite pathologic behavior in interpersonal relations with none of the above neurotic patterns.

6. Latent or overt psychosis.

Table 15 indicates that as the severity of psychopathologic symptoms as diagnosed by the psychiatrist increases, military effectiveness decreases. The "well integrated" category, signifying an absence of deviant history or abnormal findings, identifies a superior group in which 90 per cent or more rendered effective service. The performances of those with borderline or mild abnormalities such as "neurotic personality" and "suggestive neurosis" were only somewhat less effective than the average

TABLE 15. *Psychopathology and military performance**

Category	Number of inductees	Per cent performing satisfactory duty
Well integrated	273	93
Neurotic personality	131	88
Suggestive neurosis	38	84
Pathologic personality	38	81
Overt neurosis	22	68
Latent and overt psychosis	3	0
Total group	505	89

*Level of statistical significance .001

of the entire group. An interesting result was obtained in the "pathologic personality" group. Although this category includes aggressive, impulsive persons who frequently resort to anti-social behavior and usually have a marginal or poor preservice record, over 80 per cent of those so classified performed useful military service. Although these individuals are often considered to be poor garrison or peacetime soldiers, this finding confirms

the general impression of many psychiatrists that aggressive, unstable personnel often perform creditably under combat and other wartime circumstances. The group judged as having "overt neurosis" had preservice or current disabling neurotic illness. It is noteworthy that two thirds of these subjects rendered satisfactory duty. It is difficult to form firm conclusions from the three individuals who were diagnosed as having latent or overt psychoses. When psychopathologic symptoms are severe and grossly evident, such men should be rejected for military service. However, none of the three subjects were discharged as clinically psychotic. They did exhibit inadequate behavior, and two received administrative types of discharge for unsuitability.

INTELLIGENCE AND MILITARY PERFORMANCE

Intellectual ability is a traditional measuring device of fitness for both civilian employment and military duty. In order to qualify for military service, selectees must be morally fit, obtain a required score on the Armed Forces Qualification Test (AFQT), and meet prescribed medical standards. The usual rejection rates for each requirement are indicated by the results of preinduction examinations during the first year of the Korean conflict (table 16).

TABLE 16. *Results of preinduction examinations under the Selective Service Extension Act of 1950^{1a} (July 1950 through June 1951)*

Results of examination	Per cent of inductees
Not acceptable	
For medical reasons only	15.0
Failed AFQT and medical	3.9
Failed AFQT only	15.2
Administrative disqualification*	1.0
Acceptable	64.9

*Morally unfit, based on previous criminal behavior in most cases.

From the above data, it is clear that failure to pass the AFQT is a major cause of disqualification for military service. Essentially a modified intelligence test battery, the AFQT was introduced in 1950 to meet the needs of the three armed services for a single standard designed to estimate learning potential. Under this standard, individuals could be classified according to their

ability to absorb military training. From the AFQT score, the following groups were devised:

Group	Percentile score
1	93-100
2	65-92
3	31-64
4	10-30
5	0-9

Persons who score in group 5 are generally rejected for military service because they are considered untrainable by the usual methods of military instruction. In practice some selectees who failed to score above group 5 were "administratively" accepted. These were individuals whose AFQT score was inconsistent with their educational and work attainments or individuals whose motivation for the test was presumed poor.

The material of this study provided an opportunity to assay the usefulness of the AFQT in predicting military performance. Approximately 11 per cent of the subjects scored in group 5 of the AFQT. These subjects must be regarded as representing a superior level of those who failed the AFQT, since there must have been educational, work achievement, or other factors which influenced induction officials to accept them. It is believed that the performance of group 5 subjects in this study could provide some indication of the potential military usefulness of others who failed the AFQT and were thereby eliminated at induction. The relationship of AFQT results and performance is shown in table 17.

TABLE 17. *AFQT results and military performance**

Group	Number	Per cent giving satisfactory service**
1	47	94
2	98	95
3	150	90
4	148	86
5	58	80

*Level of statistical significance .001

**Four cases unknown

These results demonstrate a significant positive relationship of the AFQT groupings to military performance, but ability of the AFQT to identify potential unsatisfactory soldiers is questionable since 80 per cent of group 5 subjects rendered adequate duty. In this respect the AFQT did not demonstrate any greater accuracy than several elements of the psychiatric examination.

It is of interest to compare the efficiency of the AFQT with other measures of intellectual capacity. The examining psychiatrists in this study also rated the intelligence of each subject by the clinical impression that was obtained at the interview.

From the results shown in table 18 it is evident that intelligence as judged by the psychiatrist was also significantly related to military effectiveness. However, except for the small number considered to be deficient, clinical estimation of the subjects' intelligence was less efficient than the AFQT.

TABLE 18. *Clinical estimation of intelligence and military performance**

Category	Number	Per cent giving satisfactory duty
Definitely superior	38	95
Average or above (not superior)	360	91
Below average	95	81
Deficient	12	58

*Level of statistical significance .001

Another measure of intelligence is educational attainment. Table 19 indicates that low educational attainment (0 to 7th

TABLE 19. *Educational attainment and military performance**

Educational level completed	Number	Per cent giving satisfactory duty
High school or better (12 or more grades)	298	95
9th to 11th grade	115	84
8th grade	48	83
0 to 7th grade	44	68

*Level of statistical significance .001

grade) was a better predictor of unsatisfactory performance than the corresponding group 5 of the AFQT. High educational level and AFQT groups 1 and 2 were equally effective in the selection of a superior group who rendered 95 per cent satisfactory duty. However, educational criteria placed 298 subjects in the superior group in contrast to only 145 subjects in groups 1 and 2 of the AFQT score. Scholastic achievement is more than an index of endowed and acquired knowledge, for it is also a valid record of prior adjustment in a disciplined and structured environment. Success in school requires not only intellectual ability but reasonable compliance to authority, some capacity to tolerate frustration, and sufficient maturity to relinquish immediate goals for later and more socially desirable objectives, all of which are similar to requirements for adequate adjustment in a military setting.

COMMENTS AND CONCLUSIONS

This study tested a major and unresolved question in military psychiatry; namely, can qualified psychiatrists, given a reasonable period of interview time, efficiently predict the future military usefulness of newly inducted draftees or enlistees? Psychiatric selection as such was not directly investigated since the subjects who participated in the project had been medically screened and otherwise found acceptable for military service. Nevertheless, the results of this study are pertinent to the problems of psychiatric selection, for the following reasons: (1) If it is demonstrated that psychiatric impressions are obtained at the inception of military service and are found to have little or no predictive relationship with subsequent performance, these data would constitute strong evidence for doubting the practical value of psychiatric screening. (2) If certain components of the mental examination are found to be more significantly correlated with military effectiveness than the over-all impression of the psychiatrist, the proper use of this information could enhance the reliability of psychiatric selection methods.

The results of this study can be summarized by the following conclusions:

- 1. Psychiatric and psychologic criteria were unable to efficiently identify the potentially unsatisfactory soldier.*

Only 25 per cent of the psychiatrist's predictions of unsatisfactory service proved to be correct, whereas their estimations of satisfactory duty achieved 90 per cent accuracy. Similar results were obtained by training officer prediction, the AFQT score, and several items of the psychiatric examination. This relative inability to properly identify the potential military failure can be ascribed to one or more of the following inherent sources of error in psychiatric prediction.

Efficient psychiatric screening requires an unusually high degree of accuracy. As demonstrated in this study and similar investigations, 85 to 90 per cent of military personnel render adequate service. It is necessary to obtain 95 per cent or better correct predictions in order to justify rejection for psychiatric reasons, except in those individuals who are obviously unfit by virtue of gross mental defect or disease. Thus, from a purely statistical standpoint, psychiatric selection faces a formidable task. Only a small minority of candidates can be rejected, and these individuals must have a strong likelihood of noneffective performance, regardless of assignment or other circumstances.

The element of time markedly influences the accuracy of prediction for unsatisfactory service. When the future military performance of inductees is estimated for a long duration of time (over 6 months), there is a sharp decrease in the number of correct predictions for below-average and poor duty. This effect of time is clearly illustrated in table 8 (Part 1) of this study, in which 8 of the 9 subjects who were judged to render poor function in the Zone of the Interior are correctly identified. All of these military failures occurred in the initial five months of service, and three subjects were being processed for discharge at the time of the psychiatric examination. In sharp contrast were the results of prediction for overseas and combat assignments which involved subjects who had completed five to six months of training. In those groups, forecasts of unsatisfactory performance were rarely correct (tables 4 through 7, Part 1). It is evident that gross errors in estimating long-term military adjustment are inevitable since a sufficiency of time permits environmental changes and other situational circumstances to exert a profound influence on motivation and behavior which cannot be predetermined. Because of the foregoing reasons, psychiatrists can hope to make valid predictions of unsatisfactory service only for brief periods of time under known and relatively uniform environmental conditions, such as the training phase.

Professional differences among psychiatrists influence prediction. The six examining psychiatrists of this study, although fully qualified by training and experience, nevertheless exhibited individual patterns of predicting military performance. Among the psychiatrists there was considerable variation in both the type and proportion of subjects estimated to render unsatisfactory duty. This aspect of psychiatric selection will be more fully explored in a later report.

2. Psychiatric criteria can identify groups of varying military effectiveness.

The results of this study indicate that relative degrees of predisposition or adaptability to military stress can be demon-

strated in groups of individuals. Certain psychological and sociological data that include school and work record; educational attainment; community, social, and recreational adjustment; the AFQT; judgment of line officers, and the clinical impression of the psychiatrist were found to be significantly related to military performance. By using any of the foregoing criteria, inductees could be classified into one of the following categories (based upon percentage of effective individuals); namely, (1) superior, from 90 to 95 per cent; (2) average, from 80 to 90 per cent; and (3) inferior, from 70 to 80 per cent.

Predictors that contained some measurement of intellectual ability provided the most practical index of potential military effectiveness. This conclusion is supported by findings that school record, educational level, the AFQT, and intelligence ratings by psychiatrists are highly correlated with each other and as individual rating devices gave better predictive relationships to military performance than other background data. Educational attainment was perhaps the best predictor of the intellectual measures. This information achieved a useful discrimination among the subjects for it placed the largest proportion (60 per cent of the total) in a superior group and correctly predicted the highest percentage of unsatisfactory duty in the inferior category (tables 17 through 19). Moreover, educational level is a relatively simple and concrete type of information that can be obtained from the inductee with a minimum of distortion, although, admittedly, standards of education do vary in the various geographic regions of the United States.

That inductee or selectee groups of varying efficiency can be identified by psychiatric data has also been demonstrated by Aita^{4,5,10,11} and others. Indeed it is this aspect of psychiatric prediction which has given rise to the optimistic statements made by Wittson and Hunt¹⁶ regarding the validity and usefulness of psychiatric screening. Their contentions may be correct if the objective of psychiatric selection is to insure the largest proportion of effective servicemen without regard for the number of potentially satisfactory individuals who will be eliminated by such a process. Screening procedures of this type may be justified in the selection of officer candidates or men for highly specialized tasks, or in maintaining a relatively small cadre type Army where the limited number of individuals required make it profitable to exclude "inferior" or even "average" categories. Also, rejectees under such a program are not necessarily lost to the service. However, the huge manpower requirements of a general mobilization will not permit the losses that would occur if predisposition standards such as outlined above were put in practice. For example, in "inferior" groups the removal of three potential failures

would also eliminate seven others who were capable of satisfactory military service. In order to meet the needs of the armed services during wartime, psychiatric selection methods must be sufficiently accurate to identify an inferior group, more than 50 per cent of whom will inevitably become a burden to the military effort.

SUMMARY

Psychiatrists, the AFQT, and various components of the mental examination were unable to efficiently identify potential military failures. From the standpoint of general mobilization, these results indicate that further investigative efforts should be undertaken during this peacetime era in order to insure more accurate methods of psychiatric screening because they will be vitally needed in the event of another major conflict.

ACKNOWLEDGMENT: The authors are grateful to Mrs. Evelyn Bowman for her help in gathering the data, and to M/Sgt. Herman A. Becker for his help in the statistical computations.

THE "COMMON" MAN

"The patient who is a living detective-story may also be, I suggested, a poem of many parts that can, from time to time, reflect the light of sublimity. This you may find hard to credit when you examine some shrivelled little man with hammer-toes and a smoker's cough; but even he, even the most drably insignificant of your patients, will have had some experience of the wonder and mystery in which we live, and confidently he can expect more. He was born, and he will die; and no one who has seen birth and death can deny that 'fearfully and wonderfully are we made,' or dispute the mystery that envelops us and, at the end, gives to the meanest a moment of dignity.

CUP AND REPLACEMENT ARTHROPLASTIES

Experiences in an Army Hospital

JAMES D. CASKIE, *Lieutenant Colonel, MC, USA*

JOSEPH W. BATCH, *Colonel, MC, USA*

SINCE the popularization of hip arthroplasty with the vitallium cup method of Smith-Petersen,¹ and more recently with the replacement prosthesis methods of Judet,² Eicher,³ Moore,⁴ Thomson,⁵ Naden-Rieth,⁶ and others,⁷⁻¹⁰ much has been written on each of these methods as a means of treating various conditions affecting the hip joint. The study herein reported was undertaken to compare the various methods employed in this hospital, where individual orthopedic surgeons have used different methods of arthroplasty.

TABLE 1. *Pathologic hip conditions treated at Brooke Army Hospital (1949-1955)*

Hip condition	Number
Fractures (all kinds)	224
Aseptic necrosis	10
Nonunion, fractures	39
Dislocations, traumatic	93
Dislocations, congenital	72
Ankylosis	49
Gunshot wounds	13
Arthritis	23
Tumors	5
Degenerative joint disease	5
Total	583

From 1949 through 1955, 583 pathologic conditions involving the hip joint were encountered (table 1). Of these 583 hip conditions, 43 (in 40 patients) were deemed amenable to treatment with 19 cup and 24 replacement prosthesis arthroplasties. The conditions for which these arthroplasties were performed are listed in table 2.

From Brooke Army Hospital, Fort Sam Houston, Tex. Lt. Col. Caskie is now assigned to Fitzsimons Army Hospital, Denver, Colo.

Total	19	24

INDICATIONS

Initially in this series, cup arthroplasties were employed exclusively; during the early 1950's replacement prostheses began to be utilized; and more recently, with a crystallization of indications for the type of treatment, cup and replacement prostheses have been utilized about equally.

In general, whenever only the head of the femur was damaged, cup arthroplasty was employed. A Judet type prosthesis was used when the condition of the head precluded nailing, bone graft, and osteotomy and where sufficient length of neck remained. When the head and neck were destroyed, an intramedullary type of prosthesis was employed (table 3).

TABLE 3. *Types of arthroplasties performed by years*

Year	Cup	Judet	Thomson	Moore	Eicher	Naden-Rieth
1949-1950	6					
1950-1951	3	4				
1951-1952	3	8				
1952-1953	1		1	3	1*	
1953-1954	3	1		1		1
1954-1955	3			3		1
Total	19	13	1	7	1	2

*This replaced one of the Judet prostheses inserted during 1950-1951.

The principal conditions for which cup arthroplasties were performed were aseptic necrosis of the femoral head, traumatic arthritis, and osteoarthritis. Prostheses were utilized primarily

for fresh, comminuted fractures of the head of the femur in the younger age group; fresh, comminuted fractures of the head and neck in the older age group; and persistent nonunion of fractures of the neck of the femur. The earlier prostheses were of the Judet type, more recently only the metallic replacement prosthesis has been employed.

There was one patient in the 50-60 year age group with bilateral cup arthroplasty, one patient in the 20-30 year age group with a bilateral Judet prosthesis, and one patient in whom an original Judet prosthesis was replaced with an Eicher prosthesis. This Judet prosthesis, originally inserted for traumatic arthritis, was an early nylon type which on removal showed marked roughening of the head portion and areas that appeared to have been worn down as if sandpapered during joint motion. Seventeen patients were female and 23 were male, with an average age of 33.8 years in the cup group and 49.4 years in the prosthesis group (table 4).

A variety of approaches and modifications were employed, but the posterolateral approach was considered to be more functional, technically easier, and less traumatic, allowing earlier rehabilitation.

COMPLICATIONS AND FOLLOW-UPS

In this series of 43 operations performed on 40 patients, 4 patients were lost to follow-up. Sixteen patients with 17 cup arthroplasties have been followed an average of 31.8 months, and 20 patients with 22 replacement prostheses have been followed an average of 29.7 months (table 5).

There were 28 complications—12 in the cup arthroplasty group and 16 in the prosthetic replacement group. The complications, which compare favorably in number and type with other similar series,^{11,12} are listed in table 6. They include 3 dislocations of the hip, 4 fractures of the neck or trochanter including 1 fracture dislocation in a Judet prosthesis, 2 cases of thrombophlebitis, 2 sciatic nerve injuries, and 4 infections or reinfections. Three of these were reinfections in old septic hips, which in two cases ultimately resulted in satisfactory ankylosis. There were no deaths in the series, although two patients have subsequently died—one patient four years after insertion of a Judet prosthesis and the other one nine months after the insertion of a Moore prosthesis. Pain, although listed as a complication, was slight in nature in three patients and was not a major factor resulting in limitation of motion or function. One patient with a Moore prosthesis was entirely relieved of pain by an obturator neurectomy. In the five fractures that were encountered, three occurred in the reduction of the prosthesis at time of surgery and two resulted from falls. There was one fracture dislocation in which the fracture eventually healed with the Judet prosthesis dislocated. The

TABLE 4. *Types of arthroplasties performed by age of patient*

Total	19		2		13		7		1		1		43

remaining fractures healed, but two resulted in marked limitation of motion, one in a cup arthroplasty and one in a Judet prosthesis. The remaining dislocations produced no problems other than the required secondary reduction, and both ultimately showed excellent results. Both patients in whom thrombophlebitis was a complication recovered; one returned to duty and was capable of playing 18 holes of golf.

TABLE 5. *Average follow-up time*

Duration of follow-up (months)	Type of arthroplasty	
	Cup	Protheses
6	1	3
12	2	1
24	6	7
36	2	5
48	3	2

Thrombophlebitis		1	1			2
Limitation of motion	2					2
Sciatic nerve injury	1	1				2
Arthritis		1				1
Myositis ossificans		2				2
Total	12	11	2	1	2	28

RESULTS

In spite of a large number of complications, the final results in the follow-up cases were satisfactory (table 7). In the prosthetic replacement group, 86.3 per cent, and in the cup arthroplasty group, 76.4 per cent were considered to have excellent or good results. In evaluating the end results, range of motion, gait, freedom from pain and limp, and functional capacity were considered. The average range of motion of the hip in patients

with a prosthesis was 85° of flexion and 19° of abduction. In those patients who had a cup arthroplasty, the average range of motion was 89° of flexion and 21° of abduction. One patient with a Judet prosthesis and one patient with a cup arthroplasty complained unusually of pain and limp, but in both cases there was shortening of more than 1 inch. The patient with the Judet prosthesis obtained marked relief and improvement in gait after a lift was applied to the shoe. One patient with cup arthroplasty who had 2½ inches of shortening was given a 1-inch shoe lift, with marked improvement in gait and decrease in pain. This patient returned to duty as a traction and cast-room technician. Two patients with sciatic nerve damage walked well with foot-drop spring braces. One of them recovered totally and after two years discarded his brace.

TABLE 7. *Results of arthroplasties*

Type of arthroplasty	Result					Total
	Excellent	Good	Fair	Poor	No follow-up	
Moore	4	2	1			7
Eicher	1					1
Thomson		1				1
Naden-Rieth	2					2
Judet	5	4		2	2	13
Cup	9	4		4	2	19
Total	21	11	1	6	4	43

SUMMARY

Of a total of 583 pathologic hip conditions, 43 conditions in 40 patients were treated by cup or prosthetic replacement arthroplasties. Although a large number of complications were encountered, the end results in both the prosthetic replacement and cup arthroplasty groups were considered satisfactory. This was particularly true when the proper surgical procedure was selected for the indications present in the individual patient, with consideration of cup arthroplasty in the younger age group and prosthetic replacement in the older age group.

FRACTURES OF THE FIRST RIB

"In dealing with closed thoracic injuries, especially those produced by high speed automotive accidents, one is obligated to search carefully for evidence of first rib fracture, which may be easily overlooked before callus formation begins.

"Patients suffering such fractures, without early manifestations of mediastinal lesion, must be thoroughly examined at frequent intervals; for at least two years following injury. Each examination should include an x-ray of the chest.

"Widening of the superior mediastinal shadow in the vicinity of the aortic arch following chest injury should be considered a sign of possible incomplete rupture of the aorta, or other great vessel, from which aneurysm may develop."

ON THE READING OF MEDICAL LITERATURE

With Remarks on "The Derailment of Reason"

ALAN GREGG, M. D.

WHEN I was a student in Harvard Medical School, in 1915, I was piqued because I heard frequent praise of the Harvard Law School and rarely anything comparable regarding the Medical School. So I decided to cut my classes for three days and go to Law School lectures. It was worth it. I was surprised and deeply impressed to see how much attention was given in the Law School to learning *how* to think, as contrasted with learning *what* to think. In essence it seemed that the difference was between the dynamic and the static—how to think prepared you for the future, what to think recorded the past.

I have begun with this story and the distinction between learning how to think and learning what to think, because I believe that the cardinal requirement for effective reading of medical literature is discrimination, and discrimination depends directly on learning how to think. Even today our medical schools pay little or no attention to this essential skill.

In 1928 the organizer of the British Medical Research Council, Sir Walter Fletcher, asked me, "What do you think about the medical curriculum?" It appeared clear to him that the factual additions to knowledge made by medical science had already passed the capabilities of even the best students to master in four years, and there was no reason to suppose either that the important facts would become fewer, or that another year or two could be added to the medical school's share in the preparation for medicine. He thought that the only solution would be found in a totally fresh review of medical education and the curriculum thereof. He suggested that attention be given first of all to choosing the capacities or abilities essential to every practitioner, researcher, or teacher. Once these capacities had been agreed on, we could devote the curriculum to strengthening and refining them, leaving to the years of practical clinical or laboratory experience as much as possible of the memorizing of facts and the acquirement of skill.

Presented as the Fifth Annual Harold Wellington Smith Guest Lecture, U. S. Naval Medical School, Bethesda, Md., 28 April 1955.

Dr. Gregg was for 21 years Director for the Medical Sciences and now is Vice President of The Rockefeller Foundation, 49 W. 49th St., New York 20, N. Y.

I do not remember whether he named these capacities, but after long reflection I would suggest that they are these: the capacity to observe, the capacity to reason from your own observations, the ability to compare your observations and reasoning with the observations and reasoning of others, and, at quite a different level of performance, the ability to put yourself in the place of the patient—to acquire or develop compassion. You can readily see that the capacity to read medical literature forms a large share of the task of comparing your observations and reasoning with that of others, and let me add that the best—not the *only*, but the *best*—time to read medical literature is after you have done some observing and reasoning of your own, and not as a substitute for it.

When I say reading I mean critical reading. Even as you read this sentence (if you are a discriminating reader) you will say "critical of whom and of what?" My answer would be: critical of the author, whoever he be, and of his reasoning as well. The classic definition of rhetoric throws delightful light on this problem, for it says, "Rhetoric is the art of conveying conviction without resort to logic." Shades of the Detail Men! What a deft warning! It is even possible that if you begin by learning to read other people's writing critically you may thereby learn, even though it be at long last, to be effectively critical of what you yourself say and write.

The question "critical of what?" puts its roots into a larger area and to a greater depth. I have found much illumination in a remark attributed to Oscar Wilde to the effect that "all criticism is a form of autobiography." For example, General von Blücher's critical appraisal of Paris tells us more about Blücher than it does of Paris. He said of Paris, "Was fur plundern!" We are usually only half aware of how often and how much our past individual experience affects our capacity to evaluate as well as to reason. Nor do we always realize the subtlety of such influences; they often supply us with major assumptions that are quick and plausible but completely wrong. The physician who bases his conclusions on the experience of civilian practice can disagree both honestly and correctly with a colleague whose practice in the Armed Forces has given him a radically different experience.

Scarcely ever can one find a mountain that looks the same from the north as it does from the south. Reality is like that; it has many aspects and can only be fully portrayed by views that are not identical nor even similar, because they are views from different points of the compass. Here appears the major argument for reading; namely, that it makes available to you glimpses of truth that you have not seen. In binocular vision or a stereoscopic camera, the two images are not identical; and from the very fact

that they are *not* the same, a new sense, that of distance, becomes possible. The gains from reading usually come from the contrast between what the author has observed or concluded and what you have noted and inferred.

But sometimes you read about work in a field of which you have had no experience. What then? Well, rather obviously, you are in that case in need of a clear and comprehensible exposition, rather than the type Lord Balfour had in mind when he spoke of "things that would have been clearer if they had not been explained." Authors whom I find worth reading use description and narration to tell what something is, and definitions to tell what it is not. The hallmarks of a good exposition are that it translates or formulates *the less familiar into terms that are more familiar*; it translates *the obscure into the clear, the variant into the constant, the complex into the simple, the vague into the precise, forms into functions, and states into forces*.

Before expanding such a condensed statement and to anticipate your possible objection that you don't see how all this can bear upon the question of how to read medical literature, let me say that if an author follows none of these requirements in the first few pages of his article, I save a wonderful amount of time by refusing to read further. With the almost fantastic amount of reading we all should do, knowing what not to read becomes a cardinal point of progress in the general task of learning how to read. Some sort of selection is necessary, and I find that it is better to base one's reading on the quality of the author's mind than to select it on the title or the field of his experience. I would therefore suggest a few particulars to keep in mind when you start to read a scientific article.

First, an author of a scientific article fails in his purpose if he puts his ideas, even though they may be familiar to him, into terms that are quite unfamiliar to most of his readers. (There is one qualification to be made on this point that I will mention later.) I saw once in a psychoanalytic journal this statement: "Music is pure libido symbolism lacking objectification or cathexis." And some of you will remember Dr. Johnson's definition of a cough as "a spasm of the diaphragm vellicated by some sharp serosity." It is the reader's need—if not his right—to have the unfamiliar made familiar and the obscure made clear.

Another desideratum in medical literature is that the constant be shown as lying behind the variant. The capacity to detect and to convey this kind of clarification often improves as a result of some measure of sophistication in regard to the mathematics of probability. I would be glad to see solid geometry disappear from secondary and college curricula in favor of an equally rigorous study of the mathematics of probability, and would welcome

a wider acquaintance on the part of medical scientists with rhythmic and cyclical phenomena and the technics of detecting their occurrence and their intervals. F. R. Dewey and his associates are doing pioneer work in this field that for the most part appears in "Cycles," a monthly report of the Foundation for the Study of Cycles.

The scientific mind so frequently simplifies the complex by means of a formula, that if an article you read performs exactly the opposite and makes the simple more complicated, it deserves to be regarded with suspicion. I am less certain regarding two more characteristics of a good scientific article, perhaps because they are rarely to be found, rather than because they are trivial. Indeed they are anything but trivial. When form can be translated into terms of function, or states of being into terms of forces, we are near the cutting edge of the scimitar of science.

Lastly, one of the most important functions of good medical literature is to render the vague more precise. The psychologist, E. B. Holt, said, "A word that has many connotations denotes nothing, and a word that denotes anything cannot have connotations." For example, the word water has many connotations, but H_2O denotes just one chemical compound. Experience in putting that dictum to the test has suggested to me the thesis that one of the essential differences between scientific language and literary language consists of the fact that scientists express themselves in denotative terms, and literary artists—particularly the poets—have mastered the connotations of words.

Now all these comments point to an exceedingly interesting subject, namely notational systems. Many sciences develop their own signs and symbols, and unless we become thoroughly familiar with the notational system of a particular science, we find reading it extremely tiring and are all too ready to declare that what we read as beginners fails completely to put the less familiar into the more familiar, the complex into the simple, the obscure into the clear, the connotative into denotative terms, the variant into the constant, or the vague into the precise. Getting accustomed to symbols requires much effort, but using them effectively rewards the user remarkably. For this reason, we usually do not stop to wonder whether the symbols are really adequate for their purpose, forgetting that explanations in a notational system that is not adapted to the subject to be explained become needlessly complicated and hard to grasp. Think of trying to record the operations of the Stock Exchange in musical notation! It seems to me that there are at least two fields, endocrinology and serology, where we have not yet found the right type of symbols or denotative terms for the kind of thinking that is needed.

True familiarity with the symbols involved in some branch of science serves to protect us from glibness in using them. Not

long ago Mr. Fred McNamara of the Bureau of the Budget asked me if I knew what a billion dollars was. I replied that I could write the figure and that the word billion has one meaning in Europe and quite a different one in North America, but that I really did not know what a billion dollars was, so he told me: "A packet of a thousand \$1,000 dollar bills eight inches high is a million dollars; a billion dollars is a pile of \$1,000 bills 111 feet higher than the Washington Monument." For all its precision and its effectiveness, the decimal notation tempts one to glibness—and incomprehension.

Much could be said about notational systems and how they work, but perhaps their best effect is in drawing our attention to the kind of thinking that we use in medical science. Because I believe that explicit attention to this thinking will provide the most valuable ways to read or refuse to read medical literature, I would like to explore a little further our methods of making observations and sensible inferences. Probably a brief narrative will serve my purpose.

When I was taking the introductory course in pathology in 1913, I had the good fortune to have Dr. Howard Karsner as a teacher. Dr. Karsner, then as now, could pack a formidable amount of information into a very short space of time when he lectured, and I was disturbed by my failure to write fast enough to keep up with what he was saying. One night I had the somewhat vain-glorious idea that if one Gregg could invent a shorthand system, why couldn't another? So I devised symbols for organs and organ tissues, and for such concepts as atrophy, hypertrophy, infiltration, inflammation, induration, and necrosis, and found that they covered the nouns most in use. The adjectives needed related to size, form, weight, position, staining properties, and consistency, together with such concepts as normal and abnormal, acute and chronic, rare and frequent. The adverbs referring to time (quickly or slowly), to quantity, and to frequency were the commonest adverbs used in pathology. The most commonly used verbs were: *causes* or *is caused by*, *follows* or *is followed by*, *shows* or *is found*, *is accompanied by*, *contains* or *is found in*. To my surprise and considerable interest, these nouns, adjectives, adverbs, and verbs usually conveyed a substantial part of the concepts and the statements of an introductory course in pathology.

Soon after this invigorating discovery came a haunting disappointment. Statements put into my shorthand were clear but they were not cogent. They were comprehensible but not convincing. What was wrong? The answer to that question did not come quickly, but it contained, I think, the best sieve through which to sift the first page or two of anything you read, if you want to test the author's reliability. It deals with what adjectives

and adverbs you have a right to expect in almost any serious writing in the medical sciences.

Consider the statement: "Mosquitoes transmit malaria." Of such a statement one can say that it reports a brilliant discovery and that it is profoundly true and important, but also one can say that as a statement it is distressingly unsatisfactory. What is needed are qualifying modifiers such as *all* or *some*, for both the subject and object. For the verb, such modifiers as *always* or *sometimes* may be required. Finally, the word *only* may be needed as a modifier for subject, verb, or object. When the correctly selected qualifying words have been put in, you have something cogent, resembling cabinet work rather than three logs lashed together with a liana vine. The accurate choice of the correct modifiers of the subject, verb, and object in the case of the unchallengeable statement, "mosquitoes transmit malaria," makes the final statement conclusive as well as clear. Broadly speaking, if you pick up a reprint and the subjects, predicates, and objects have no qualifiers of the above-mentioned sort, you are not in first-class intellectual company, and you proceed with the reading at your own risk. So much for the best sieve I know of for separating the wheat from the chaff in medical literature.

One of the most frequent purposes of scientific papers relates to finding the causes of some phenomenon or condition, but most medical scientists seem completely oblivious (or ignorant) of the fact that results usually come from many causes, not one. I doubt if I could exaggerate my feelings regarding the stupidity we show in so frequently assuming that one result is due to only one cause. We ought to use the word *why* in the plural and ask, "Whys is this patient in coma?" not, "Why is this patient in coma?" The next time you hear someone say anything that attributes a single cause for some event, ask yourself if he means the predisposing, the precipitating, or the perpetuating cause? And how many causes of each of these kinds are involved? A particular case of a fractured jaw in a sailor may be the result of convergent causes—no letters from home, too much alcohol, the loan of a car by a friend, a dark night, an oncoming car on a road covered with ice at a curve, the fact that the left-hand rule is used in the British Isles, new brake linings, a skid, and a telephone pole. These constitute the whys, not the why, of a fractured jaw. It is a cataract of consequences. Take out any one of these whys and the accident would not have occurred. When will we wake up to the importance of multiple causation? Some prefer to call it convergent causation. I am as sorry for those physicians who have never heard of "Occam's Razor" as I am for those who have never heard of Gillette's.

Whenever you hear it stated that A causes B, you can get a sort of intellectual setting up drill by saying to yourself, "I

long ago Mr. Fred McNamara of the Bureau of the Budget asked me if I know what a billion dollars was. I replied that I could write the figure and that the word billion has one meaning in Europe and quite a different one in North America, but that I really did not know what a billion dollars was, so he told me: "A packet of a thousand \$1,000 dollar bills eight inches high is a million dollars; a billion dollars is a pile of \$1,000 bills 111 feet higher than the Washington Monument." These constitute the whys, not the why, of a fractured jaw. It is a cataract of consequences. Take out any one of these whys and the accident would not have occurred. When will we wake up to the importance of multiple causation? Some prefer to call it convergent causation. I am as sorry for those physicians who have never heard of "Occam's Razor" as I am for those who have never heard of Gillette's.

Whenever you hear it stated that A causes B, you can get a sort of intellectual setting up drill by saying to yourself, "I

wonder if it isn't wiser to say that B causes A?" For example, it is fairly probable that in the next six months you will hear it said that some acquaintance "has had a nervous breakdown from overwork." Ah! There is an implication that overwork has caused a nervous breakdown. How would it be to reverse the interpretation and conclude that the man overworked because of self-doubt or overconscientiousness, which are early symptoms of some kinds of oncoming nervous breakdowns? Perhaps depression or insecurity inclined him to stay at the office until a quarter of eight instead of quitting at five o'clock as he used to . . . and then to a quarter of ten, and then to midnight. And at a later stage, when he had exhausted his sense of fatigue, staying all night at work. I have found this particular form of mental gymnastics not only diverting but at times remarkably rewarding—which is more than I could honestly say of the usual kind of gymnastics.

Quite naturally, if we are unaware of the frequency of multiple causation, we are the easy victims of plausibility; we stop looking for more than one cause if the one that occurs to us seems plausible. Let me give you, to illustrate the subtle way in which plausibility can kill true curiosity, an experience that I will disguise by changing the scene to a distant city. I was attending a medical lecture in Liverpool, England, given by an Irish physician. He failed to hold my attention. I began to watch a device behind the speaker which flashed the names of doctors in the audience who were wanted on the telephone. I noted that an unusually large number of the names were Irish; 17 out of 19. Now 13 out of 19 would not have been above the probabilities of chance, but 17 out of 19 was well above being a chance event. What could explain that? Being amused by the number of plausible explanations, I listed them. Here is the list, and any one of the reasons might have seemed so plausible as to stop any further inquiry:

1. The Irish population in Liverpool is unusually large.
2. The medical profession in Liverpool contains a very high proportion of Irishmen.
3. Irish doctors are notably conscientious about keeping up with advances in medicine by attending lectures.
4. Irish doctors want to be seen attending lectures.
5. Irish doctors are unusually compassionate and ready to sacrifice even such opportunities as professional lectures to the whims of their patients.
6. Irish physicians employ nurses who need close supervision or who are excessively conscientious.
7. The patients of Irish physicians want their money's worth and are not phlegmatic or submissive.

8. The lecture hall was in the Irish sector of Liverpool.

9. Irish doctors flocked to hear the lecturer because he was an Irishman and a graduate of the National at Dublin.

10. The Irish doctors in Liverpool want their names to be better known and crave the appearance of being busy.

11. The lecture was on a disease very common among Irish people.

12. The prestige of the Irish doctors in Liverpool has become so great that English physicians are changing their names—for, mark you, all I was seeing was Irish *names*, not necessarily Irish *men*.

As a last remark on the risks of mere plausibility, let me call your attention to the fact that all these circumstances *might* have been true simultaneously.

As another example of plausibility, let us assume that a substance not frequently found in urine has been reported in one of your patients. Among the plausible explanations are: (1) It was ingested and when present is routinely excreted by the kidneys. (2) It is normally present in the blood and is usually put out only by a so-called leaky kidney. (3) It is normally stored in the bones and has been released by the ingestion of some other substance, *e. g.*, lead released from the long bones by the ingestion of large quantities of phosphoric acid. (4) It is usually excreted by some other organ such as the lungs or the skin, but this mechanism is interfered with and the kidney takes over the task. (5) It was not ingested but is the product of faulty metabolism, *e. g.*, an adrenal neoplasm. (6) There was another patient with the same name and the specimens were mixed.

From these examples you can see that an article in any current journal that fails to list all of the plausible explanations for an event should show cause for limiting its attention to just one of them.

Let us pass from the pitfalls of plausibility to the equally misleading failures due to an ignorance of the laws of probability. We cannot rely upon good horse sense in such matters. What do you think are the probabilities that at a dinner attended by 20 people there will be at least one pair who share the same day of the same month as their birthday? Are you surprised to know that it is better than a 50-50 chance? More precisely it is a 52.05 chance. Does that disturb your confidence in your common sense? It did mine.

The commonest failure I note in most medical articles is the assumption that in a short series of cases, say 41, a positive result in 26 is evidence of something more than chance. I can offer you in this connection a simple formula the mathematician R. A. Fisher gave me as a reliable criterion for drawing sound

inferences from small numbers, *i. e.*, a good working rule to apply. Let the total number of cases be called $a + b$, a standing for the number of positives and b the number of negatives. You are reasonably safe if $\frac{(a - b)^2}{a + b}$ equals 4 or more. Thus, in a series

of 41 cases, if 26 are positives and 15 are negatives, the result works out to only 2.9, and 26 out of 41 is not significant because it does not significantly exceed mere chance. But if there had been 27 positives and 14 negatives, then $\frac{(a - b)^2}{a + b}$ would have

equaled 4, which begins to be significant. This formula is readily applied to many a medical report, and I have found it a valuable criterion to apply in reading case reports.

Some day you may have time to kill. Flip a penny 1,500 times and keep a record of the results. I did this once and got 755 heads and 745 tails. Very reassuring! But in that series I had one run of 12 heads in succession. Supposing that a run of 12 successive cures, or at least remissions, should be observed when first using a new drug for patients with multiple sclerosis. How could one fail to become a convert to such a drug? It is a very sobering reflection, and has led me to believe that one of the great needs of medicine, and particularly for men in research work, is a course in evidence. Intensive drill in distinguishing between hunches, surmises, varying degrees of probability, and the nature of certainty or proof could be an extraordinarily valuable experience for most of us.

One more suggestion and I am through. When a train wreck occurs, the railroad officials want to find out the whys and the hows: was it due to a defective rail, roadbed, bridge, signal, item of rolling stock, or human reaction? Now, when as medical scientists we try to keep our thinking, observations, and inferences on the right track, we too are fatefully subject to one or another kind of derailment of our reasoning. The different kinds of the derailment of reasoning deserve closer study than they are getting. Indeed, I had thought of entitling this lecture, "The Derailment of Reason," but I thought that if I could call it, "On the Reading of Medical Literature," I could interest you first in the errors of others' thinking and then you could, with these errors in mind, turn your attention in slow crescendo to the mistakes that all of us make. Moreover, a new kind of approach lies at hand. The history of medicine is loaded with false interpretations of biologic phenomena, inferences that were but derailments of reasoning. Clinical observations have been wonderfully good, in comparison to the inferences drawn. Let us study, clarify, and classify such derailments of interpretation or reasoning, in order to improve our performance in keeping on the track. For as George Santayana said, "He who is disposed to ignore history must be prepared to repeat it."

CONCURRENCE IN PSYCHIATRIC DIAGNOSIS

WILLIAM A. HUNT, *Commander, MSC, USN*
CECIL L. WITTSON, *Commander, MC, USN*

THE QUESTION of diagnostic concurrence, or agreement among psychiatrists, is one that has concerned us in our continuing study of the theory and practice of naval psychiatric selection.^{1,2} Since the diagnostic process is basic to any selection procedure, we have considered its implications^{3,4} and experimentally studied some of its characteristics.^{5,6} This article compares the diagnoses given a group of recruits under psychiatric observation during basic training with the diagnoses assigned when they were subsequently discharged during later active duty. It not only studies diagnostic agreement among psychiatrists, but offers further information on the discharge channels typical of different types of psychiatric cases.

PROCEDURE

During World War II those recruits undergoing basic training at the Newport Naval Training Center who were suspected of serious psychiatric involvement were admitted to the observation ward of the psychiatric unit for careful study before disposition. Those borderline patients considered capable of rendering adequate service were returned to active duty. Subsequently many of these received psychiatric discharges from the fleet, offering an opportunity of comparing the discharge diagnosis with that assigned on the observation ward at Newport. The present experimental sample thus consists of men diagnosed on the observation ward at Newport, sent to duty, and subsequently discharged during service with the fleet. It should be stressed that all these were borderline cases and therefore presumably more difficult to diagnose.^{7,8} Also, the Newport diagnosis was not entered in the health record and thus could not have prejudiced the final discharge diagnosis. Moreover, the time elapsing between the original diagnosis and ultimate discharge ran in some cases to as long as three years.

Since the psychiatrists on the Newport ward were not held to any specific diagnostic nomenclature while the final fleet diagnosis had to conform to official naval nomenclature, it was felt that any comparison involving specific, detailed diagnoses would

CONCURRENCE IN PSYCHIATRIC DIAGNOSIS

WILLIAM A. HUNT, *Commander, MC, USN*
CICIL L. WHITE, *Commander, MC, USN*

THE QUESTION of diagnostic concurrence, or agreement among psychiatrists, is one that has concerned us in our continuing study of the theory and practice of naval psychiatric selection.^{1,2} Since the diagnostic process is basic to any selection procedure, we have considered its implications^{3,4} and experimentally studied some of its characteristics.^{5,6} This article compares the diagnoses given a group of recruits under psychiatric observation during basic training with the diagnoses assigned when they were subsequently discharged during later active duty. It not only studies diagnostic agreement among psychiatrists, but offers further information on the discharge channels typical of different types of psychiatric cases.

PROCEDURE

During World War II those recruits undergoing basic training at the Newport Naval Training Center who were suspected of serious psychiatric involvement were admitted to the observation ward of the psychiatric unit for careful study before disposition. Those borderline patients considered capable of rendering adequate service were returned to active duty. Subsequently many of these received psychiatric discharges from the fleet, offering an opportunity of comparing the discharge diagnosis with that assigned on the observation ward at Newport. The present experimental sample thus consists of men diagnosed on the observation ward at Newport, sent to duty, and subsequently discharged during service with the fleet. It should be stressed that all these were borderline cases and therefore presumably more difficult to diagnose.^{7,8} Also, the Newport diagnosis was not entered in the health record and thus could not have prejudiced the final discharge diagnosis. Moreover, the time elapsing between the original diagnosis and ultimate discharge ran in some cases to as long as three years.

Since the psychiatrists on the Newport ward were not held to any specific diagnostic nomenclature while the final fleet diagnosis had to conform to official naval nomenclature, it was felt that any comparison involving specific, detailed diagnoses would

This study is part of a larger project being conducted through the Department of Psychology of Northwestern University, Evanston, Ill., under contract with the Office of Naval Research.

be unfair. For comparison we therefore selected the broad categories of psychoneurosis (PN) and personality disorder (PD). It would have been desirable to include a psychotic category, but all men falling in this category were automatically discharged at Newport and none were sent on to the fleet. No organic cases were included in the study. Since disciplinary and general medical discharges are also known disposal outlets for psychiatric involvement, we included such final fleet discharges in our study, hoping that interesting differences in our groups might appear. Thus, the criteria for inclusion in the sample studied were that the man must have been diagnosed on the observation ward during basic training at Newport, subsequently sent to duty, and later discharged from the fleet for psychiatric, medical, or disciplinary reasons.

The sample studied consisted of 82 recruits originally diagnosed as psychoneurotic and 213 diagnosed as having a personality disorder. As a control we included 28 men showing symptoms of psychoneurosis, such as anxiety, tachycardia, tremor, depression, et cetera, but whose symptoms were not sufficiently pronounced to permit them to be definitely diagnosed as psychoneurotic; and 82 men showing symptoms typical of the personality disorders, such as immaturity, history of many arrests, nomadism, et cetera, but who were not definitely diagnosable as such. Also included as a control were 40 men studied on the observation ward and judged to be normal.

RESULTS

The results are presented in table 1, which gives the percentage of each original diagnostic group falling in each of the final discharge categories. Comparing the original with the final psychiatric diagnosis, we find that of all the cases originally diagnosed as psychoneurotic and subsequently receiving a psychiatric discharge from the fleet, approximately one half received a diagnosis of psychoneurosis, with the majority of the remainder being discharged as personality disorders. In view of the borderline nature of the cases and the amount of time elapsing between the original and the final diagnosis, the diagnostic agreement would seem to be fair and would indicate some efficiency in the original diagnostic performance. Some confusion obviously exists between the psychoneurotic and personality disorder categories, however. These results are confirmed by the group which showed psychoneurotic symptoms but which could not be definitely diagnosed as psychoneurotic. Turning to the group with personality disorders, we find that approximately three quarters of those subsequently receiving a psychiatric discharge were discharged as personality disorders. Again, this is confirmed by the group with only symptoms of a personality disorder. The agreement here is certainly good. It would appear

that the diagnosis of personality disorder is a more reliable one than that of psychoneurosis, a finding that confirms those of a previous study of ours.⁴ The personality disorders seem to be more reliably identified than the psychoneuroses.

TABLE 1. Agreement between Newport diagnosis and final discharge diagnosis

Newport diagnosis	Number of diagnoses	Percentage subsequent to diagnosis					
		PN*	PD**	PN+PD***	Other	Medical	Disciplinary
Psychoneurosis	92	27	26	1	4	5	37
Psychoneurotic symptoms	28	43	19	0	2	5	29
Personality disorder	213	9	28	2	4	43	14
Personality disorder symptoms	62	7	32	0	4	17	40
Normal controls	40	5	5	5	5	10	70

*PN = Psychoneurosis

**PD = Personality disorder

***PN+PD = All disciplinary discharges

When we look at the other medical and disciplinary discharges, we find some interesting differences between the groups. The psychoneurotics are significantly less apt to receive a disciplinary discharge than are the men with personality disorders, who show a marked tendency to disciplinary difficulties. The psychoneurotics are even less of a disciplinary problem than the normal men. On the other hand, the psychoneurotics tend to be more of a medical problem than those with personality disorders. These findings confirm another investigation by us.⁴ Moreover, these differences are in agreement with the clinical interpretation of the disorders and show that the psychiatric diagnosis predicts important aspects of the individual's social behavior. As would be expected by the definition of "normal," psychiatric and disciplinary discharges are relatively infrequent outlets for our normal control group.

These findings on disciplinary and medical discharges demonstrate the importance of considering these disposal channels in any study of the psychiatric serviceability of military personnel. They also raise a question concerning the study of the reliability of psychiatric diagnosis; i. e., if a recruit is diagnosed as an asocial personality and subsequently receives a bad conduct discharge, or if he is diagnosed as psychoneurotic and subsequently receives a medical discharge for some psychosomatic complaint, are not these examples of diagnostic concurrence rather than the disagreement superficially implied by the difference in the channels of disposal?

SUMMARY

The study of a group of recruits, originally diagnosed as having psychoneurotic or personality disorders but subsequently sent to duty as borderline cases, who were later discharged from the fleet for psychiatric, other medical, or disciplinary reasons shows close concurrence in psychiatric diagnosis. As compared with the psychoneurotics, the patients with personality disorders were much more of a disciplinary problem and somewhat less of a medical problem.

TECHNIC OF CREMASTER MUSCLE DISSECTION IN INGUINAL HERNIOPLASTY

FELIX P. BALLENGER, *Captain, MC, USN*

THE PROPER method of dissecting the cremaster muscle when performing inguinal hernioplasty has been little discussed, yet in many cases it presents a real problem if an adequate repair is to be accomplished. In performing inguinal hernioplasties, and also when observing other surgeons performing this operation, I have noted difficulty in accurately suturing the fascia of the transversalis muscle to the shelving border of the inguinal ligament about the spermatic cord at the internal inguinal ring when the usual methods of dissection of the cremaster fibers were used. If the cremaster fibers are split in the line of their descent, or if they are allowed to continue to encircle or cover the cord structures in any manner, they will invariably obstruct the proper placement of sutures about the spermatic cord at the internal inguinal ring.

OPERATIVE TECHNIC

In order to avoid the difficulties created by the presence of the cremaster muscle in this part of the repair, I have developed a technic for dissection in this region which completely removes the obstructions caused by the cremaster fibers, and also, in cases of recurrent hernia and large hernia, obviates excision of the cremaster in order to accomplish adequate repair. The following technic for dissection and repair of an inguinal hernia is therefore recommended, as I have used it in a large number of cases with invariable ease of suture placement and excellent results.

1. The usual inguinal skin incision is made.

2. The external oblique fascia is incised and opened in the line of its fibers into the apex of the external inguinal ring. This incision is carried about one and one-half inches above the internal abdominal ring and well down over the pubic tubercle in the external spermatic fascia.

3. The cremaster fibers are dissected free from the inguinal ligament from the pubic tubercle to one inch above the internal

SUMMARY

The study of a group of recruits, originally diagnosed as having psychoneurotic or personality disorders but subsequently sent to duty as borderline cases, who were later discharged from the fleet for psychiatric, other medical, or disciplinary reasons shows close concurrence in psychiatric diagnosis. As compared with the psychoneurotics, the patients with personality disorders were much more of a disciplinary problem and somewhat less of a medical problem.

THE SHIFTING INCIDENCE OF PSYCHOSIS

Manic-depressive psychosis and general paresis are definitely on the decline since about 1935. Rates for general paresis are much higher for men than women, but the relative difference is less in recent years than formerly. Manic-depressive psychosis rates are higher for women than men. Alcoholic psychoses show, with some exceptions, a generally rising trend, with rates that are very much higher for men than women.

TECHNIC OF CREMASTER MUSCLE DISSECTION IN INGUINAL HERNIOPLASTY

FELIX P. BALLENGER, *Captain, MC, USN*

THE PROPER method of dissecting the cremaster muscle when performing inguinal hernioplasty has been little discussed, yet in many cases it presents a real problem if an adequate repair is to be accomplished. In performing inguinal hernioplasties, and also when observing other surgeons performing this operation, I have noted difficulty in accurately suturing the fascia of the transversalis muscle to the shelving border of the inguinal ligament about the spermatic cord at the internal inguinal ring when the usual methods of dissection of the cremaster fibers were used. If the cremaster fibers are split in the line of their descent, or if they are allowed to continue to encircle or cover the cord structures in any manner, they will invariably obstruct the proper placement of sutures about the spermatic cord at the internal inguinal ring.

OPERATIVE TECHNIC

In order to avoid the difficulties created by the presence of the cremaster muscle in this part of the repair, I have developed a technic for dissection in this region which completely removes the obstructions caused by the cremaster fibers, and also, in cases of recurrent hernia and large hernia, obviates excision of the cremaster in order to accomplish adequate repair. The following technic for dissection and repair of an inguinal hernia is therefore recommended, as I have used it in a large number of cases with invariable ease of suture placement and excellent results.

1. The usual inguinal skin incision is made.
2. The external oblique fascia is incised and opened in the line of its fibers into the apex of the external inguinal ring. This incision is carried about one and one-half inches above the internal abdominal ring and well down over the pubic tubercle in the external spermatic fascia.
3. The cremaster fibers are dissected free from the inguinal ligament from the pubic tubercle to one inch above the internal

abdominal ring (fig. 1). It is important in this dissection to see that all fibers are completely detached from the inguinal ligament.

Figure 1. Beginning the dissection of the cremaster muscle. The point of the scissors is shown under the lower edge of the cremaster; at this site the cremaster is detached from its origin.

This lower border of the cremaster is then elevated and the dissection continued to elevate the cremaster muscle in its entirety from the external spermatic fascia and underlying cord (fig. 2). The entire cremaster, including its origin from the internal oblique muscle, is then retracted upward. This exposes the spermatic cord covered by the internal spermatic fascia (fig. 2).

4. The spermatic cord and its internal spermatic fascia covering can then be dissected completely free from the floor of the inguinal canal from the internal abdominal ring to a point below the pubic tubercle. When this has been accomplished all areolar tissue is removed from the inguinal canal and its floor (fig. 2).

5. The internal spermatic fascia is then incised in a line with the spermatic cord and the hernia sac can easily be brought up, dissected out completely, its neck transfixed and ligated high inside the internal abdominal ring, the sac excised, and the stump

allowed to retract upward. If, however, a direct hernia sac is present, it can be handled by whatever method seems appropriate such as dissection, high ligation, and excision or by imbrication and infolding.

Figure 2. The cremaster has been elevated from the cord and the cord dissected from the floor of the inguinal canal.

6. After the sac, or sacs in the case of a "Pantaloon" type, have been adequately removed or imbricated, the repair can then be proceeded with. The transversalis fascia is secured in the floor of the inguinal canal with Allis forceps, and the border of the transversalis fascia is sutured to the shelving border of the inguinal ligament with interrupted No. 00 cotton sutures (fig. 3). The sutures are placed from the medial angle lateralwards, being certain to secure the first suture into the fascia overlying the pubic tubercle. As placement of the sutures upward and outward proceeds, it becomes obvious that they can be placed on either side of the spermatic cord at the internal abdominal ring with ease without incorporating fibers of the cremaster muscle, because the cremaster and internal oblique muscles are now being retracted upward completely out of the way (figs. 3 and 4). By placing 6 to 8 sutures below and medial to the cord and 2 or 3

Figure 3. Retraction upward of cremaster muscle permits easy placement of sutures in transversalis fascia and inguinal ligament.

above or lateral to it, a snug repair around the spermatic cord usually can be obtained. In infants and children this layer of repair is not necessary and is omitted. I believe that many recurrences of indirect inguinal hernias occur because of inaccurate placement of sutures and failure to secure an adequate, snug repair about the spermatic cord. This defect can easily be avoided by using this technic of dissecting the cremaster and repairing the floor of the inguinal canal.

7. The spermatic cord is then replaced in the inguinal canal and the cremaster replaced over the cord and sutured to the inguinal ligament in its normal anatomic relationship (fig. 5). However, if it is thought desirable, the cord can be transplanted completely to the subcutaneous tissues in the Halsted repair. If the cord is replaced in the canal and the cremaster sutured over it as above described, the external oblique fascia and external spermatic fascia are then closed with interrupted No.

0000 cotton sutures and the subcutaneous tissue and skin closed with the same material. If the Halsted procedure is done the external oblique fascia is sutured beneath the spermatic cord,

Figure 4. All sutures have been tied, apposing the transversalis fascia to the inguinal ligament.

allowing the cord to emerge through this suture line at a point about one-half to three-fourths inches lateral to the internal abdominal ring. A bed of subcutaneous tissue is then sutured underneath the cord, between it and the external oblique fascia, and subcutaneous tissue and skin are closed over the cord, using No. 0000 cotton sutures throughout.

SUMMARY

A technic for dissecting the cremaster muscle from the external spermatic fascia and spermatic cord and retracting it upward along with the internal oblique muscle allows easier placement

Figure 5. The cremaster has been replaced over the cord in its normal anatomic position, and is shown here with its lower border resutured to the inguinal ligament.

of sutures in the transversalis fascia and inguinal ligament. This technic obviates the incorporation of the cremaster fibers in the suture above and lateral to the spermatic cord and, I believe, makes a more accurate and stable repair of this portion of the inguinal canal floor.

The specialist is a man who fears the other subjects.

ADVANCES IN TRAINING THE NEUROPSYCHIATRIC TECHNICIAN

DENNIE L. BRIGGS, *Lieutenant, MSC, USN*
NORMA R. WOOD, *Lieutenant, NC, USN*

CHANGING technics in the treatment of hospitalized psychiatric patients have necessitated a reassessment of the role of the nursing staff. In the past, members of the nursing staff usually considered their primary duties to be providing the custodial and housekeeping aspects of patient care, and the patient was allowed little opportunity to assist in his own treatment. Today, however, their responsibilities are centered mainly about providing an atmosphere conducive to treatment, and their duties include working with patients to a greater degree. The importance of interpersonal relations in treatment is increasingly recognized and fostered in hospitals using social psychiatric technics.

We feel that although the roles of the psychiatric nurse and the corpsman are not yet fully defined, steps should be taken to provide a continuing educational program that will give them every opportunity to learn more of treatment procedures, interpersonal relations, and the dynamics of their own personalities, and to share in developing their own niche in the treatment program. It was believed that existing educational opportunities needed revision in the light of recent developments in other hospitals and of our own experience in operating an acute admissions ward without use of restraints and with only occasional use of sedatives.¹

In a period of 10 months, approximately 1,000 patients were admitted to the acute admissions ward of this hospital, and it was not found necessary to put any patient in a seclusion room.² However, due to the fears and anxieties of various staff members, patients were put in the quiet rooms on five occasions. In order to operate such a unit, it becomes necessary to revise traditional methods of training and to provide means whereby corpsmen can learn to recognize and handle their own anxieties.

From U. S. Naval Hospital, Oakland, Calif. Lt. Briggs is now assigned to the U. S. Naval Hospital, Navy 3923, FPO, San Francisco, Calif.

CURRICULUM

The curriculum of the Neuropsychiatric Technicians School at this command has been previously described by Kahn.³ This school was established during World War II when emphasis was placed on screening out obvious psychiatric misfits and on the survey of those who had psychiatric breakdowns while on active duty.⁴ The training included highly specialized procedures such as deep insulin coma and electroconvulsive therapy and made much use of didactic lectures dealing with theories concerning the dynamics and treatment of specific mental disorders. Although there was occasional use of "milieu therapy" and brief psychotherapy, the psychiatric service and the course of instruction for technicians was primarily oriented toward physical treatment and various other suppressive and repressive technics such as sedation and restraint. In a period of less than two years the orientation changed to one in which relationship therapy was stressed on all wards, even those with acutely disturbed patients.⁵ The transition was not always an easy one, and it involved a major reorganization of the course of instruction in the school.

Formalized didactic lectures, we found, contributed to a certain kind of defensiveness on the part of the corpsman which often made him feel extremely uncomfortable, as though he was expected to interpret psychologic material to the patient. As his training was not adequate for this, he many times found himself in an extremely frustrating situation and often resorted to suppressive measures designed to control his own anxiety rather than that of the patient. This, too, was a result of his earlier medical training in which he was taught to regard the patient as a semi-invalid whose treatment involved active physical measures.

The new student has many preconceived ideas as to the nature of mental illness, the role of the technician, and exactly what composes psychiatric treatment itself. Two of our students have vividly pointed out some of these misconceptions and have shown the importance of working with the feelings and attitudes of the staff as well as those of the patient.⁷⁻⁹

One problem with which we were particularly concerned was the corpsmen's lack of participation in the patients' groups and in the ward staff meetings, and their failure to attend psychiatric staff meetings. We became convinced that, rather than stimulating them, we were contributing to their anxiety by creating an atmosphere in which they thought they had to know more than was actually expected of them.

Recognizing these needs, we instituted some time ago a weekly group discussion with the students held by a psychiatrist and

a psychologist, and more recently by the nursing supervisor, the chief of nursing service of the hospital, and a psychologist. We were rewarded by evidences of the students' growth, demonstrated by their increasing ability to express some of their feelings and anxieties. Frequently students, after working at other activities, have written us that they considered this experience to be one of the most valuable in their training.

COUNSELING PROGRAM

When the student begins his training program he is assigned to a psychiatrist on the staff for counseling purposes. If the student was formerly on the staff of this hospital, he is allowed to choose the physician he would like to work with. Students are given appointments for an initial interview; additional appointments are up to the student and the psychiatrist. In some instances students have been introduced to individual psychotherapy, which has lasted throughout their stay at this hospital and has been continued with civilian therapists after the student's release from service. These instances are most encouraging, because when the student realizes he has personal problems to cope with and seeks help with them, he is in a better position to work with patients and with staff members. The nursing instructor acts as an educational counselor as well and assists the students with their anxieties regarding their work. When educational problems become mixed with emotional difficulties, the student is encouraged to discuss these with his therapist.

More recently we have introduced two other teaching methods that have aided considerably in helping the student to take a more active part in the treatment program.

"BIG BROTHER" PROGRAM

We felt that the student needed to know patients as human beings rather than as disease entities and decided to try assigning each student a patient early in his training. The student preferably first sees the patient on one of the admissions wards and follows him throughout his stay in the hospital. He sees the patient as often as his schedule and own interest will allow with the purpose of getting to know him and finding out all he can about him. Sessions are provided for discussion of the patients, and the students are encouraged to keep notes of their contacts. At the end of the course, they prepare a summary of their impressions of the patients. Several of the patients have made marked improvement, which has served as a most effective demonstration to the student of the real value of relationships in treatment. The student provides the patient with a healthy model to identify with and feels no pressure to "treat" the patient.

At the students' request, we have modified our teaching program to include an hour per day of group discussion held by vari-

ous staff nurses to deal with the daily anxieties aroused in caring for patients. These hours have proved to be extremely rewarding, and a great deal of discussion ensues, often prolonged beyond the assigned time.

Students have chronically complained that they do not feel part of the service, and we have found that we have inadvertently contributed to this feeling by not giving them certain rights and privileges which are accorded even the most inexperienced and untrained staff members. We have taken steps to make the student feel more a part of the psychiatric service by affording him wherever possible the same opportunities as a permanent staff member. We have held seminars twice a week for the entire staff that provide an opportunity for continual growth for everyone as well as indoctrination of new staff members, and that allow as little distinction between student technicians and others as possible. We believe this will contribute greatly to the therapeutic atmosphere of the service as a whole and will result in even better patient care than in the past.

We believe that the success of methods in the newly emerging field of social psychiatry in mental hospitals justifies looking into our traditional teaching and ward management procedures and at this time see two main areas in psychiatric nursing and treatment which should be developed further.

SOCIAL THERAPY

The idea of the social therapist originated with Dr. Maxwell Jones and his work at the Social Rehabilitation Unit at Belmont Hospital in England. Here, young girls with various backgrounds are taught how to care for psychiatric patients in a relatively short period of time while working as members of the staff. They remain in the unit for only six or eight months and yet achieve a remarkably high degree of therapeutic skill. They attend a series of seminars dealing with normal growth and development given by a permanent staff member and have additional opportunities to learn about interpersonal relations in their daily contacts with patients. Their daily instruction periods enable them to deal with their own anxieties and curiosities when these are most meaningful; thus their training helps them to cope with their own problems while aiding in the treatment process. Their primary role is relating to patients and encouraging them to communicate their feelings to others in order that they may be understood and helped by other staff members and by the other patients. Pressure is thus not exerted on them to interpret psychological material.¹⁰ This orientation away from interpretation is an extremely important one, as we have pointed out.¹¹

WARD MANAGEMENT

It follows that when free communication is developed and social anxiety is lessened, both patients and the staff feel less pressure, and a truly therapeutic community can emerge. *The degree of behavioral change possible within relatively short periods of time in such an atmosphere is limited only by the abilities of the staff to share in the communication process.* The results of this kind of treatment are evident even in the chronic behavior and character disorders¹² where social rehabilitation is accomplished sometimes in four or five months, in persons with life-long histories of great maladjustment, as well as in the debilitating neurotic disorders. One frequently hears staff members comment on the "quietness" of their ward or group, as if this were the criterion of successful treatment. Use of sedatives and restraining technics in the past created a sense of security in the staff but seldom considered the welfare of the patient.

It appears that when communication among members of the staff and between staff and patients is improved, the running of the ward itself becomes therapeutic, as the patient more and more participates in his own treatment. The staff must be able to give up some of their functions without guilt and of necessity have to "unlearn" many aspects of their roles. It is accomplished informally by dealing with anxieties as they arise.

Treatment, as we see it, consists of providing the patient with healthy people as models for his own behavior and of working out means for constant communication of his feelings to others. By healthy people we mean real people—each with his own individuality, anxieties, and interests, but free to express these qualities rather than allow them to interfere in his relationships with others. Communication increases the ability to tolerate others and to relate to them in a realistic manner, thereby decreasing the likelihood of having to act out impulses and feelings. All relationships in the hospital then become potentials for therapy if skill in using them is developed.

ACKNOWLEDGEMENTS: We would like to thank Capt. Robert R. Deen, MC, USN, Lt. Comdr. Lina Stearns, NC, USN, Lt. Margaret Shaw, NC, USN, Comdr. Myrtle Warner, NC, USN, and Dr. Irving D. Berg for encouragement, advice, and active participation in the program.

DENTAL HYGIENE AND SEX

"The real test of a patient's patience is the dental chair. Here a patient, no matter how calm he pretends to be, signals his tension by slight psychomotor movements which the dentist can detect. And, according to a dental survey made, appropriately, by *Dental Survey*, women make better dental patients than men. As a matter of fact they also take better care of their teeth generally. It seems that in pre-adolescence, little boys consider any type of washing—whether in the mouth or behind the ears—a feminine frill. Worse than that, they believe that a defiance of mother's instructions to wash the teeth, is a symbol of manliness. Then through certain psychiatric mechanisms, not to be disclosed in this family periodical, the growing boy carries this low opinion of dental hygiene right into adult life. The adolescent may slick down his hair and clean his fingernails while preparing for a date; but he apparently feels no need for washing in places where the fruit of his industry is not so visible. To the girl, on the other hand, cleanliness and body care seem to be basic virtues. All of which may account for the fact that women are better patients than men. Or are they?"

ACUTE SUPPURATIVE ARTHRITIS OF THE HIP IN CHILDREN

JAMES B. JONES, *Captain, USAF (MC)*
REGINALD C. RAMSAY, *Captain, USAF (MC)*

ACUTE suppurative arthritis is not uncommon, and in any medical facility where a large number of sick children are treated it can be anticipated that a few patients will develop a pyogenic infection of a joint. The pathogenesis is similar to acute hematogenous osteomyelitis, the bacteria being blood borne from some primary focus of infection. The offending organisms are staphylococcus, streptococcus, pneumococcus, *Hemophilus influenzae* bacillus, gonococcus, meningococcus, and occasionally coliform bacteria.¹ Any of the larger joints may be affected, but, except for gonococcal arthritis, as a rule only one of them is involved. With the present widespread use of antibiotic drugs for the treatment of primary infections, such as boils, acute tonsillitis, and otitis media, many cases of acute suppurative arthritis are either prevented or are aborted before clinical recognition is possible. When an acute inflammatory process does involve a joint, it is easily detected by signs of increased local heat, redness, swelling, tenderness, and pain on motion. However, when the hip or spine is involved the clinician must rely on more subtle findings because of the larger amount of surrounding soft tissue.

Suppurative arthritis of the hip, if neglected, has disastrous sequelae. The capitular epiphysis of the femur may be destroyed, and it is common for the hip to become dislocated.^{2,3} In other cases the articular cartilage may be destroyed, resulting in either fibrous or bony ankylosis in a position of deformity.⁴⁻⁶ It is therefore highly desirable that the diagnosis of acute suppurative arthritis of the hip be established early in its course, so that effective therapeutic measures may be instituted before irreversible changes in the joint structures can ensue.⁵ The purpose of this article is to discuss methods of early recognition of acute suppurative arthritis of the hip and to present two illustrative cases.

SIGNS AND SYMPTOMS

The diagnosis should be considered in any child who has a fever, develops a protective limp, and refuses to walk or to move about normally. A history of a preceding febrile illness is common, or the child may still be suffering from an infection. There may be a relationship to trauma, and this is apt to be misleading. Any trauma would direct attention to the painful part but probably does not play a significant role in the pathogenesis. The patient will be irritable and restless, and will cry, especially with any movement. Inasmuch as any motion may be transmitted to the affected hip joint, it will be difficult for the parent and for the examiner to ascertain the site of the pain. A child of three years of age or older may be able to indicate the location of his difficulty, but if this is not the case, the physician must rely on careful observation and examination.

The capsule of the hip joint is more relaxed in the flexed, abducted, externally rotated position (the so-called "frog position"). If there is increased fluid within the joint the child will automatically tend to hold his leg in this position (fig. 1A). Any motion which will tighten the capsule and decrease the space will produce increased tension within the joint and accentuate the pain. The most important clinical finding, therefore, is the observation that the child is more comfortable with one hip held toward the frog position. With the hip supported in this position the other joints of the lower extremity can be examined without unduly upsetting the child (fig. 1B). It is especially important to rule out any disease in the knee joint. The simultaneous examination of both hips is most satisfactory (fig. 1C). By grasping the knees, the hips are held in the frog position and gently abducted and extended. Reflex muscular resistance will be detected on the affected side and the child will cry out. An uninvolved hip joint can be moved without resistance and without pain. In addition, it may be noted that tenderness on palpation is present over the hip joint.

These findings are indicative of increased fluid or synovial thickening within the hip joint. In children, several conditions can produce these changes. Nonspecific synovitis of the hip is the most frequent differential diagnosis to be considered. With nonspecific synovitis, not a well-understood clinical entity, the child usually does not have a fever, although frequently it occurs following a febrile illness. There is a protective limp and guarding of the hip. The signs and symptoms are not alarming and last for only a few days. One wonders if some of these cases might not be actual abortive bacterial infections.

Identical to nonspecific synovitis is the early stage of Legg-Calvé-Perthes disease, which cannot be definitely diagnosed until roentgenographic changes can be demonstrated in the capit-

Figure 1. (A) Frog position of the right hip. (B) With the hip held in the frog position, the other joints of the lower extremity can be more easily examined. (C) Simultaneous examination of both hips is most satisfactory.

ular epiphysis of the femur.' It is for this reason that all cases of nonspecific synovitis should be followed carefully and repeated roentgenographic studies made if there is persistence of any signs or symptoms referable to the hip joint. Tuberculosis, which can simulate an acute pyogenic infection, may be most difficult to rule out, and one must rely on the laboratory for final proof. Also to be considered in the differential diagnosis are rheumatoid arthritis and rheumatic fever.

Roentgenograms of the hips should be obtained in every suspected case. The capsular outline is frequently visible and, if more prominent or bulging on the affected side, is of diagnostic significance. One should also look carefully for the appearance of widening of the joint space (fig. 2). Any osseous involvement may be indicative of an osteomyelitic process.

Figure 2 (case 1). The initial roentgenogram of the hips showed widening of the joint space on the right. This is highly suggestive of increased fluid within the joint. The capsular outline cannot be visualized.

Routine laboratory studies will usually reveal a polymorphonuclear leukocytosis, although this finding was not present with one of our patients. It is to be expected that the erythrocyte sedimentation rate will be elevated.

ASPIRATION OF THE HIP JOINT

Although the diagnosis may be suspected from the foregoing, it cannot be established without aspiration of the hip joint. Not only is aspiration diagnostic, but it also is an all-important therapeutic step. Smear and culture of the joint fluid will prove or disprove the presence of a pyogenic infection, and antibiotic sensitivity studies will guide the physician in his therapeutic program.

Aspiration of the hip joint is not difficult, contrary to common opinion, and when the joint is distended with fluid, is surprisingly easy. The following method is recommended. The skin and subcutaneous tissue lateral to the femoral pulse and parallel to the prominence of the greater trochanter are infiltrated with one of the local anesthetic agents such as procaine hydrochloride or Xylocaine Hydrochloride (brand of lidocaine hydrochloride). A long 20- or 21-gage needle on a syringe filled with the local anesthetic agent is then directed toward the hip joint, keeping in mind that the head of the femur is directly beneath the femoral pulse and that the needle must angle superiorly to correspond to the normal angle produced by the neck of the femur (fig. 3).

Figure 3. The approach for needle aspiration of the hip joint.

When the needle encounters the anterior hip capsule, there is increased resistance to its insertion. By injecting small quantities of fluid, it can be determined when the hip joint has been entered. The joint space will accommodate only 1 or 2 ml of fluid, and the fluid will return into the syringe. It must be emphasized that if fluid does not return to the syringe the point of the needle does not lie within the hip joint. Frequently, if there is increased fluid within the hip joint, it will appear in the syringe as soon as the needle pierces the capsule. Before withdrawing the needle, it is wise to inject penicillin solution into the joint if there is any suspicion that a pyogenic infection is present.

All material obtained from the joint should be sent to the bacteriology laboratory for routine smear and culture. Specific ant

biotic sensitivity studies should be made. An immediate smear of the fluid may not only show the presence of pus cells, but may give an indication of the nature of the offending organism. One of the antibiotic drugs should be administered, although the culture and sensitivity studies may suggest changing to another drug at a later date.

It is beyond the scope of this article to discuss in detail the treatment of suppurative arthritis of the hip. However, in our opinion, the infection can be adequately controlled in most cases by specific antibiotic drugs if the diagnosis is established and effective drugs instituted early in the course of the disease. Surgical intervention can be held in abeyance until the efficacy of treatment with antibiotics alone can be determined. Open drainage is not to be condemned but should be used only if truly indicated.

CASE REPORTS

Case 1. A three-week-old male infant was admitted to this hospital because he had had fever, been irritable, and had not moved his right leg for one week. At the time of admission the infant cried constantly, especially on being moved about. Both hips were held flexed and externally rotated in a frog position. There was definite resistance to manipulation of both hips. However, the left could be brought to a more neutral position whereas there was increased resistance to extension of the right hip and the slightest attempt caused him to cry out. There was a one-degree temperature elevation. The white blood cell count on admission was 17,950 per μ l with 51 per cent neutrophils and 49 per cent lymphocytes. Roentgenograms of the hips showed the appearance of widening of the joint space on the right (fig. 2).

The day following admission to the hospital the right hip joint was aspirated. One milliliter of purulent fluid was obtained. Before withdrawing the needle, 450 mg (750,000 units) of crystalline penicillin G was injected into the joint space. Immediate smear of the fluid showed the presence of gram-negative intracellular diplococci. Two hundred and ninety-seven milligrams (300,000 units) of procaine penicillin G was administered intramuscularly twice daily for three days and then once daily for eight days. There was an obvious immediate improvement noted following the aspiration, and continued gradual improvement. At the time of discharge, 12 days after admission, the infant was actively moving both his legs and both hips could be brought to a neutral position without resistance.

Since discharge from the hospital the patient has been a healthy, normal appearing infant. Roentgenograms of the hips taken at age six months showed normal development of both hips.

Because of the nature of the infection the mother was examined. Urethral smear disclosed gram-negative intracellular diplococci. Treatment for her infection was therefore instituted.

Case 2. A three-year-old girl was admitted to this hospital because of pain in the right lower extremity and a protective limp. Two weeks prior to admission she had had an upper respiratory infection which resolved spontaneously. Her mother stated that four days before admission the child fell, following which she would not use her right leg when walking, and she ran a low-grade fever. The mother believed that the source of her child's difficulty was the right knee.

On admission to the hospital the child had a rectal temperature of 101°F. There was a marked protective limp on the right and the child held her right hip partially flexed and externally rotated. There was tenderness and muscle spasm about the right hip joint, and any attempt to extend and internally rotate the hip caused the patient to cry out with pain. The white blood cell count was 13,200 per μ l with 24 per cent neutrophils and 66 per cent lymphocytes.

The initial working diagnosis was synovitis of the right hip with rheumatic fever or rheumatoid arthritis to be excluded. Roentgenograms of the hips were negative. The erythrocyte sedimentation rate was 44 mm per hr, and C-reactive protein was 2 plus. Other laboratory tests, including antistreptolysin titer, blood culture, and an electrocardiogram were within normal limits. Two days after admission to the hospital salicylate therapy was instituted but the patient continued to have a temperature elevation ranging between 100° and 101°F, and no improvement in the hip was noted.

On the sixth hospital day the right hip joint was aspirated and 2 ml of slightly cloudy, straw-colored fluid was obtained. Before withdrawing the needle, 600 mg (1,000,000 units) of crystalline penicillin G was injected into the hip joint. Fifty milligrams of Terramycin (brand of oxytetracycline hydrochloride) was administered intramuscularly three times daily. The day following the aspiration the child's temperature spiked to 102°F and then she became afebrile. There was an immediate improvement in the child's clinical course.

The growth on the culture of the joint fluid was alpha hemolytic streptococcus, which was most sensitive to tetracycline and Chloromycetin (brand of chloramphenicol) and less sensitive to Terramycin and penicillin. Two hundred and fifty milligrams of tetracycline four times daily was given orally and the Terramycin was discontinued.

The patient continued to improve and on the 15th hospital day she was walking with only a slight limp. The tetracycline was continued for two weeks after the child was discharged. Clinical and radiologic findings of the right hip two months later were completely normal.

SUMMARY

The early recognition of acute suppurative arthritis of the hip is essential to avoid its disastrous sequelae.

The physician should become suspicious of this condition from the history of fever and voluntary protective immobility of the

hip. The patient often will maintain the involved hip in flexion, abduction, and external rotation ("frog position"). Widening of the joint space or bulging of the capsular outline may be noted on routine roentgenograms of the hip.

Nonspecific synovitis, rheumatic fever, rheumatoid arthritis, and tuberculous hip disease must be considered in the differential diagnosis.

The definitive diagnostic procedure in septic arthritis of the hip is aspiration of the hip joint. This should be performed in every suspected case. Bacteriologic examination of the joint fluid may reveal the specific pathogenic organism. Antibiotic sensitivity studies will guide the therapeutic program. The removal of purulent fluid from the joint space and the instillation of an antibiotic agent, such as penicillin, is highly beneficial until specific therapy may be started after completion of sensitivity studies.

VALUE OF PERSEVERANCE

"It is, however, a serious fault in a research worker to be too ready to drop problems as soon as he encounters a difficulty or gets seized by enthusiasm for another line of work. Generally speaking one should make every effort to complete an investigation once it has been started. The worker who repeatedly changes his problem to chase his newest bright idea is usually ineffectual."

1950. p. 131

Clinicopathologic Conference

Tripler Army Hospital, APO 438, San Francisco, Calif.*

PROGRESSIVE DYSPNEA

Summary of Clinical History. A 34-year-old electrician and painter of Portuguese extraction was admitted to the hospital complaining of shortness of breath on exertion for one month.

Except for a marked susceptibility to colds, he said he had been in good health up to three months before admission, when he noted intermittent frontal headaches and some generalized muscle aches lasting for one month, and began to cough up small amounts of greenish sputum. One month before admission he noted dyspnea on exertion, which gradually increased in severity and was associated with some weight loss and fatigability. From onset of symptoms to admission, he had lost about 25 pounds. Two weeks before admission he first noted wheezing over the upper right side of his chest, as well as hoarseness and night sweats. He denied chest or abdominal pain, orthopnea, hemoptysis, chills, allergies, nausea, vomiting, jaundice, diarrhea, dysuria, or ankle edema. His past medical history revealed few of the usual acute childhood infections. He had gonorrhea at the age of 23 and a fractured foot 4 years later. He had been discharged from the Army 5 years before for psychoneurotic symptoms. He had had no medication except for routine treatment of his colds, no tobacco, and just an "occasional" beer.

There was no known exposure to tuberculosis or coccidioidomycosis. Six months before admission the patient had a routine chest roentgenogram taken which he was told was normal.

*Brig. Gen. John F. Bohlender, MC, USA, Commanding General. From the Laboratory Service, Col. Harold E. Shuey, MC, USA, Chief.

Physical Examination. The patient was a well-developed, chronically ill male in no acute distress. His temperature was 99.4°F; pulse, 80; respirations, 26; blood pressure, 126/84 mm Hg. Examination of the eyes, ears, nose, and throat was negative. Examination of the lungs revealed impairment to percussion over both bases anteriorly and posteriorly. The diaphragm moved freely. There was increased fremitus over the right lower chest. Fine inspiratory rales and intermittent wheezes were heard over both bases anteriorly and posteriorly. The heart, abdomen, and neurologic systems were negative on examination.

Laboratory Studies. Red blood cells numbered 3.6 million per μ l. The hemoglobin measured 10.2 g per 100 ml. There were 10,200 white blood cells per μ l with 61 per cent neutrophils, 30 per cent lymphocytes, and 4 per cent eosinophils. The erythrocyte sedimentation rate was 32 mm per hour, corrected (Wintrobe). Blood chemistry studies revealed the following: serum alkaline phosphatase, 10.4 Bodansky units; serum acid phosphatase, 1.5 King and Armstrong units; serum inorganic phosphorus, 4.4 mg per 100 ml; and serum calcium, 11.4 mg per 100 ml. The cephalin-cholesterol flocculation test was negative. Serologic examination of the serum revealed a negative Kahn test and no cold agglutinins. The urinalysis was negative, with no Bence-Jones protein. The sputum was very scanty, and no acid-fast bacilli were found on repeated smears and cultures. Gastric washings were also negative for acid-fast bacilli. Skin tests with coccidioidin and histoplasmin and a PPD (second strength) tuberculin test (on two occasions) were negative. A third tuberculin test was reported as eliciting a 3-plus reaction.

Chest roentgenograms taken on admission revealed "a feathery density in each lower lung field, most marked in the medial areas. The diaphragm is not involved. The heart is not enlarged. In areas the individual densities tend to become confluent, and in the right base the possibility of honeycombing is present. The upper lung fields show no evidence of disease." Films taken two months later on the second admission showed extensive *coalescence of the densities* so that they became homogenous, completely filling the lower two thirds of both lung fields from the hilum to the periphery. There was no apparent cardiac enlargement. A gastro-intestinal series and barium enema were nonrevealing.

Except for the roentgenographic findings described above, repeated laboratory tests showed little alteration during the course of the patient's illness. The serum inorganic phosphorus dropped to 3.4 mg per 100 ml. On the day before death, the white blood cell count rose to 39,800 per μ l with 92 per cent neutrophils. No pathogenic organisms were grown on repeated cultures.

Course in Hospital. On the first admission the patient remained in the hospital for 29 days, when he signed his own release. He received only symptomatic treatment. During this stay he developed no new physical findings or symptoms. At all times inspiratory rales could be heard over both bases. He ran a persistent low-grade fever, never above 100.4°F, and cough and sputum were almost entirely absent.

For a month the patient remained at home. Cough and dyspnea gradually increased; weight loss and fatigue became marked.

The patient was readmitted with severe dyspnea and marked cyanosis of the skin and mucous membranes. The temperature was 99.8°F; pulse, 120; respirations, 40; blood pressure, 124/80 mm Hg. Some clubbing of the fingers and toes was noted. The lungs showed slight dullness to percussion over both bases. Bronchovesicular breath sounds were equal throughout. There was good motion of the diaphragm. The heart was not apparently enlarged. The heart sounds were normal. The liver edge was palpable 4.0 cm below the right costal margin and was slightly tender. There were no palpably enlarged lymph nodes. The rest of the examination was essentially negative.

Since the nature of the patient's disease was not established, treatment was symptomatic. He was given penicillin and streptomycin sulfate. Despite high oxygen concentration by tent and mask, he showed marked cyanosis and dyspnea on the slightest exertion. He suffered severe aching pains across the front of the chest which were relieved by Demerol (brand of meperidine hydrochloride). No fluid was obtained at the time of a right thoracentesis attempted shortly before death. Death came quietly 73 days after the first admission.

DISCUSSION

Doctor Pitts:* This discussion deals with a 34-year-old male who developed a relentlessly progressive illness characterized by pulmonary insufficiency, with death 8½ months following a report of a normal chest x-ray, 5½ months after the onset of symptoms, and 3½ months subsequent to the onset of dyspnea. Associated symptoms consisted of a low-grade cough with constitutional manifestations of low-grade fever, considerable weight loss, and progressive debility. Objective findings revealed bilateral diffuse pulmonary involvement which appeared patchy and symmetrical without hilar adenopathy on the initial chest roentgenogram. Cyanosis at rest or on the slightest exertion, refractory to oxygen therapy during the latter part of his clinical course, suggested an alveolar-capillary block in the absence of evidence compatible with a venous-arterial shunt. Laboratory findings of mild anemia and an elevated serum globulin are considered nonspecific.

*Maj. Forrest W. Pitts, MC, USA, Department of Medicine.

The clinical manifestations were not those of acute or chronic parenchymal suppuration or bronchiectasis, and I believe these entities may be readily excluded without further discussion. Nor does this case fit the pattern of infection due to viral or rickettsial agents. Fungus diseases such as coccidioidomycosis, histoplasmosis, and blastomycosis may appear as diffuse bilateral progressive pulmonary disease, and negative skin tests are the rule rather than the exception in the disseminated and progressively fatal forms. At this point in the discussion, serologic studies do not discourage their elimination on the basis of negative cultures, lack of extra-pulmonary involvement, and subsequent death due to asphyxia. The tuberculin conversion is difficult to explain but this finding does not fulfill the usual significance attributed to it when an attempt is made to correlate it with other key features. The only plausible explanation for an individual to die of tuberculosis with extensive pulmonary involvement, repeatedly negative cultures for *Mycobacterium tuberculosis*, and clinical manifestations of an alveolar-capillary block is that associated with the miliary form of this disease; the latter is readily excluded by the appearance and distributions of the lesions on the chest roentgenogram (fig. 1).

Other causes to be considered are obscure diffuse bilateral pulmonary diseases, including pulmonary infiltration with eosinophilia, pneumoconiosis, lipid pneumonia, lymphoma, uremia, and histiocytosis or lipogranulomatosis. These may be excluded because of the absence of expected associated findings and/or the less savage clinical course usually associated with these diseases.

Pulmonary adenomatosis (alveolar cell carcinoma, bronchiolar carcinoma) produces diffuse bilateral pulmonary lesions and an asphyxial type of death, but this condition usually runs a much more protracted course and is characterized by large quantities of clear mucoid sputum of low viscosity.

Diseases commonly associated with alveolar capillary block such as pulmonary arteriosclerosis, repeated multiple thromboses or embolization with infarctions of the pulmonary vascular bed, leukemia, sarcoidosis, beryllium granulomatosis, lymphangitic metastases, chemical pneumonia similar to that noted following inhalation of sulfur dioxide fumes, certain collagen diseases, and the type of diffuse interstitial pulmonary fibrosis described by Hamman and Rich¹ provide a more fruitful but difficult group to narrow down in the differential diagnosis. Cor pulmonale is common during the late stages of most of these entities, and I suspect the pathologist will find hypertrophy and dilatation of the right ventricle in this case, although little or nothing is stated in the protocol with reference to an electrocardiogram, cardiac fluoroscopy or evaluation of the cardiac silhouette in the lateral or oblique views, the presence or absence of distended neck veins, and dependent edema. Enlargement of the liver during the second hospitalization seems to be the only recorded manifestation of right ventricular failure.

Figure 1. Roentgenogram of the chest showing bilateral feathery densities in the medial portions of the lower lung fields.

The rapid downhill course, low-grade fever, x-ray appearance of the lesions, and lack of polycythemia lead me to exclude pulmonary arteriosclerosis. Repeated small thromboses or infarctions of the pulmonary vascular bed remain a possibility and cannot be excluded with certainty.

As an electrician, the patient may have been exposed to beryllium through contact with (now obsolete) broken fluorescent light tubes. This point in the history would be extremely important if positive, since all the features of his illness are compatible with such a diagnosis. Interestingly enough, a negative history would not exclude beryllium granulomatosis in the light of reported "neighborhood cases." However, lack of x-ray evidence of upper lobe involvement and absence

of a miliary type of lesion militates against this diagnosis as the most likely cause. Occupational exposure to sulfur dioxide gas as used in old refrigerators remains a less likely possibility and can be excluded reasonably well.

On the day prior to death, the white blood cell count was reported as 39,800 per μ l with 92 per cent neutrophils. I prefer to attribute this to an agonal leukemoid reaction rather than to myelogenous leukemia. It is difficult to conceive of a respiratory type of death from leukemia, particularly so in the absence of more severe anemia, retinal hemorrhages, and splenomegaly.

Could this be an unusual case of sarcoidosis? All of the key findings—diffuse bilateral pulmonary disease, low-grade cough and fever, alveolar capillary block, elevated serum globulin, and hepatomegaly from cor pulmonale and/or hepatic involvement—are in keeping with sarcoid. Occasionally sarcoid runs a progressive, fatal course, but for death to occur within such a brief span of time makes this possibility seem improbable. Lack of hilar or extrathoracic adenopathy and/or clear-cut involvement of other tissues or organ systems also rules heavily against sarcoid as the most likely diagnosis.

Carcinomatous lymphangitic metastases to the lung from an occult primary lesion such as that which may occur in the body or tail of the pancreas, the stomach, or the bronchus would account for all of the findings in the protocol and cannot be excluded from the final differential diagnosis with complete certainty. The x-ray appearance is not that of the "sunburst" pattern, and this factor lends considerable weight against this possibility.

Of the collagen diseases, scleroderma most frequently produces an alveolar-capillary type of block. The absence of cutaneous findings and other features readily leads one to exclude the possibility of scleroderma. Periarthritis nodosa may involve the medium-sized vessels of the lungs, subsequently producing an alveolar-capillary type of block and occasionally leading to destructive lesions in the lungs characterized by cavitation. Hypersensitivity angiitis characteristically involves the small vessels of both arteries and veins and runs a more acute course. It is not characterized by necrotizing granulomata. Hypersensitivity angiitis is usually associated with a generalized vasculitis and frequently terminates fatally from diffuse vascular involvement of uremia. A specific subtype of collagen disease was described in 1931 by Klinger³ and formulated by Wegener³ in 1939. This is characterized by necrotizing granulomatous lesions in the upper air passages or in the lung, as well as renal changes manifested by necrosis and thrombosis of loops or lobes of the glomerular capillary tuft. In addition, there is generalized vasculitis. In reviewing the literature to 1954, Fahey⁴ found 22 cases of Wegener's granulomatosis in the literature and added seven cases of his own. Absence of both renal

involvement and diffuse organ or system involvement in this case tends to rule against a collagen type of disease such as hypersensitivity angitis or Wegener's granulomatosis.

In 1944 Hamman and Rich from Johns Hopkins described four cases of acute diffuse interstitial fibrosis of the lungs of undetermined cause observed from 1931 to 1943. All cases were characterized by cough, progressive dyspnea, cyanosis, and cor pulmonale. Autopsy revealed interstitial edema and hemorrhage with few leukocytes, and enlargement of the lining alveolar cells as well as necrosis of the alveolar and bronchiolar epithelium; a hyaline membrane was noted to line the alveoli, and bacteria were absent. None had vascular lesions similar to periarteritis nodosa. The most striking feature was a progressive, extensive, diffuse interstitial proliferation of fibrous tissue throughout all portions of both lung fields. The early stage was characterized by fibroblasts, and the late stages showed mature scar tissue. Survival times from the onset of symptoms varied from one to six months. The histories of Hamman and Rich's original cases are almost identical to that of the present protocol. Since the original description, a total of 27 cases had been recorded at the time Peabody and Peabody³ wrote an editorial on this condition in December 1954. Eighteen of the 27 cases have been reported since 1950.

The cause of the Hamman-Rich type of diffuse interstitial pulmonary fibrosis is unknown. Suggested causes have ranged from recurrent episodes of viral pneumonia, chemical irritants and hypersensitivity, to a disturbance of fibrinolysis. Pathologic changes similar to the Hamman-Rich type of involvement have been reported with five fatal cases of interstitial pneumonia which occurred while the patients were receiving prolonged Apresoline (brand of hydralazine hydrochloride) and hexamethonium therapy. Characteristically, all cases have been resistant to therapy. Initially, it was believed that duration of life was limited to weeks or months. There are now two patients who have survived three years and a third reported in 1949 to have survived 13 years after the onset of symptoms. Corticotropin and cortisone had been used empirically with equivocal effect. One striking case demonstrated a remission coincident with the onset of administration of these agents and followed by a severe exacerbation when they were discontinued. Most authorities agree that once steroids are started they should be continued for life.

Although it is difficult to pick out any single diagnosis with certainty, I believe the over-all features of this case best fit a diagnosis of the Hamman-Rich type of diffuse interstitial pulmonary fibrosis.

Doctor Bratenahl: * Before presenting the pathologic findings, I would like to know what further comments any of you would like to make regarding this case; in particular, any more guesses as to the most probable diagnosis. Would anyone care to comment further on the x-ray

*Comdr. Charles G. Bratenahl, MC, USN, Naval Medical Unit, Laboratory Service.

picture (fig. 1) in this case, correlating it with the history? Might anything significant be added to the x-ray description?

Doctor Blumley:* I have nothing to add to the description of the x-ray findings as given in the protocol. While beryllium poisoning has to be thought of, the patient having been an electrician, most cases of beryllium poisoning occur in factory workers making fluorescent bulbs. The roentgenographic finding in acute cases consists of widespread fine nodular infiltrations in the lung fields. With continued exposure this can go on to the chronic form of poisoning within three to four months, characterized by large granulomatous infiltrations in the lungs. Also related to his occupation as an electrician is the possibility of chemical pneumonitis by inhalation of hydrogen chloride, as electricians commonly use hydrochloric acid to clean electrical connections prior to soldering. Symptoms resulting from such exposure are headaches, substernal pains, dyspnea, and marked cyanosis—symptoms which this patient demonstrated.

Doctor Gangerosa:** Boeck's sarcoid is at times associated with pulmonary fibrosis and active tuberculosis terminally. The latter is manifest clinically by a reversion of the tuberculin skin test from negative to positive as seen in this case. This reversion has diagnostic import, I feel. Some believe that repeated skin testing with tuberculo-protein in a tuberculin-negative individual will induce a tuberculin reaction, but Raffel¹ has shown that it is the waxy component, the lipid fraction of the tubercle bacillus, which is necessary in combination with tuberculo-protein to induce the tuberculin reaction. I, therefore, submit a diagnosis of Boeck's sarcoid with pulmonary fibrosis and active tuberculosis terminally.

Clinical diagnoses:

Undiagnosed condition manifested by bilateral pulmonary infiltrations suggestive of pulmonary adenomatosis

Dr. Pitts' diagnoses:

1. Hamman-Rich diffuse interstitial fibrosis of the lungs of undetermined cause
2. Terminal leukemoid reaction of the blood

Dr. Gangerosa's diagnoses:

1. Boeck's sarcoid, with pulmonary fibrosis
2. Active tuberculosis

PATHOLOGIC FINDINGS

Doctor Brotenohl: At autopsy the patient was a markedly emaciated 34-year-old Caucasian man. The skeletal muscles were atrophic, and there was marked lack of subcutaneous fat. Moderate clubbing of digits was noted. The heart weighed 350 grams, and the right ventricle was moderately dilated. There were 200 ml of pericardial fluid present. The heart valves were essentially normal.

***Major Nelson Blumley, MC, USA,** Assistant Chief, Radiology Service.

****Capt. Eugene J. Gangerosa, MC, USA,** Intern, Obstetrics and Gynecology Service.

The principal findings were confined to the lungs. The right weighed 1,710 grams, the left 1,600 grams. With sterile precautions, cultures of the right lung revealed *Pseudomonas aeruginosa*. There was no pleural effusion, but fresh fibrinous adhesions covered the pleura on both sides (fig. 2). Some fibrinous adhesions were noted at the left apex. The lungs appeared heavy and solid with no crepitation at all. They had a consistency almost like liver. Cut sections revealed almost homogeneous, light gray-white, rather solid lung tissue in all lobes, particularly solid in the lower lobes (fig. 3). There was no particular odor about the tissues. On slight pressure a thick, yellowish, opaque fluid oozed from the cut surface. This material was smooth and non-granular. On dropping the lung tissues into Formalin (brand of formaldehyde solution), it was noted that this material floated to the surface as oil droplets. Oil droplets were also noted in the bloody fluid remaining in the posterior thorax after removal of the lungs.

The bronchi were mostly filled with a thick, creamy material similar to that found on compressing the lungs. Some of this material was also found in the trachea. At the apex of the left lung, a red, soft area 5 cm in diameter was found containing semiliquid necrotic material and resembling a poorly walled-off abscess. Although in general the pulmonary lobular markings and other architecture of the lungs were well preserved, no definitely aerated tissue was demonstrable on gross examination. The tracheobronchial and paratracheal lymph nodes were enlarged up to 3.0 cm in diameter (fig. 2). On cut section, they appeared homogeneous and gray-white.

Microscopic sections of the lungs showed a heavy, acellular, fibrinous exudate on the pleura associated with some congestion. Innumerable large macrophages with foamy cytoplasm were found in the septae as well as filling many of the alveoli (fig. 4). Numerous young fibroblasts were also noted in the alveolar septae and proliferating within the alveoli (fig. 5). The alveoli in many areas had a cuboidal epithelial-cell type of lining (fig. 6). The lungs appeared very dense on all sections. Section from the left upper lobe in the area grossly suggesting an abscess showed considerable fibrosis but no distinct abscess. On hematoxylin-eosin sections, many of the alveoli were filled with a basophilic-staining, granular, amorphous precipitate in which were numerous small and large vacuoles (fig. 6). Frozen sections of lung stained with Sudan IV showed intensely red-staining oil droplets in these vacuoles and within the macrophages in the alveoli and alveolar septae. This fatty material did not stain with osmic acid and was not doubly refractile. Occasional conglomerate masses of reticulo-endothelial cells were noted in the alveoli, vaguely simulating giant cells; however, no true multinucleated foreign body giant cells were found. Sections of peribronchial lymph nodes showed the sinusoids crowded with fat-filled macrophages, which stained positively with Sudan IV and negatively with osmic acid.

Figure 2. Medial aspect of left lung showing fibrinous pleural reaction and enlarged gray-white hilar lymph nodes. Figure 3. Left lung in cut section showing uniform gray-white consolidation throughout.

Figure 4. High power photomicrograph of lung showing vacuolated macrophages in alveoli and thickened alveolar walls. ($\times 400$)

Figure 5. Photomicrograph of section of lung showing diffuse fibrosis of alveolar walls with lipophages and proliferating fibroblast tissue in the alveoli. ($\times 80$)

Figure 6. Photomicrograph of lung showing fibrous thickening of alveolar walls with large numbers of lipophages in the walls and alveoli, basophilic material and large and small vacuoles, and dissolved oil droplets in the alveoli. Some of the alveoli are lined by cuboidal epithelium probably derived from the bronchioles. ($\times 80$)

Shortly before this patient's death it was learned that, for a long unknown period of time before his first hospitalization, he had used large quantities of oily nose drops and possibly an oil-containing nose spray for his repeated head colds. He denied using any of this material after his initial admission and up to the time of his death.

The staining reaction of the fatty material found within the lungs in large quantities, positive for Sudan IV and negative for osmic acid, is consistent with mineral oil (liquid petrolatum) in contrast with vegetable and animal oils.⁷ Some caution in strict interpretation is necessary as the Sudan IV stain is not entirely specific for mineral oil.⁸ The pathologic findings of diffuse pulmonary fibrosis associated with large numbers of lipophages in the alveoli and interalveolar septi and the general lack of specific foreign body or inflammatory reaction are consistent with findings reported in previous cases of lipoid pneumonia due to mineral oil.

Vegetable oils, such as Lipiodol (brand of iodized poppy seed oil), sesame oil, or olive oil, usually result in little reaction of the lung tissues. These oils are slowly absorbed with little residual fibrosis. Animal oils, such as cod liver oil or halibut oil, usually cause a much

more acute reaction associated with marked fibrosis and rather striking giant cell formation in a few days. The latter type of lipoid pneumonia occurs mostly in infants, and there is usually a history of attempting to force a sick child to swallow cod liver oil against his will, possibly by holding his nose. If his reflexes are weak from illness, he tends to gag and aspirate considerable oily material. Although the reaction is quite severe, it is frequently self-limited.

Lipoid pneumonia resulting from liquid petrolatum is more often found in adults, usually elderly, and as a result of using oily nose drops. Characteristic pathologic findings consist of lipophages in the alveoli and alveolar walls surrounded by a fibrous reticulum, filling much of the air spaces and tending to concentrate in the bases of the lungs posteriorly. The elderly patient has usually employed the oily nose drops or sprays over a long period of time. When x-rays show a picture suggesting a low-grade bronchopneumonia in the bases that does not resolve and that is associated with almost no symptoms, the possibility of lipoid pneumonia should be considered. Death usually results from a secondary infection, and the diagnosis is rarely made before death. The sputum may occasionally show lipophages, but this finding is not very helpful since they may be found in various other conditions. The lungs usually appear yellowish and solid, and usually there is an absence of pleural exudate or adhesions. The fibrinous pleural exudate present in this case and the high globulin and alkaline phosphatase values reported here are puzzling features not completely explained. Are there any other questions?

Doctor Pulaski: I believe some of you may be interested in a case very similar to the one presented in this Clinicopathologic Conference. It was reported by Stanley⁹ in 1947. This was a case of pyocyaneus pneumonitis associated with lipoid pneumonia in a 73-year-old Caucasian man. He had suffered with recurrent sinusitis over a period of 16 years, and it was believed that the lipoid pneumonia resulted from his use of oily nose drops. In his case the pyocyaneus pneumonitis was much more extensive and the lipoid pneumonia much less so than in our present case. He died on the sixth day after admission. Since primary pneumonitis due to *Bacillus pyocyaneus* is a relatively rare occurrence, the interesting thought occurs as to a possible relationship between the lipoid pneumonia and pyocyaneus pneumonitis.

Pathologic diagnoses:

1. Lipoid pneumonia, secondary to the use of oily nose drops
2. Terminal pneumonitis, due to *Pseudomonas aeruginosa*

*Lt. Col. Edwin J. Pulaski, MC, USA, Assistant Chief, Department of Surgery.

ON DROWNING

"If a victim has flooded his lungs with fresh water and yet has been successfully resuscitated then it would appear certain that he would be suffering from plethora, haemodilution, electrolyte disturbance, and pulmonary oedema. Further, he would be in danger of severe renal damage from the presence of freely circulating haemoglobin. Substitution bleeding with electrolyte correction, treatment for acute kidney damage, and oxygen therapy for pulmonary oedema and lung flooding would seem to be indicated. Hypotonic saline and oxygen therapy may be of help in those saved from salt-water drowning. The almost complete absence of any clinical reports of patients requiring and receiving such treatment in the vast medical literature of today can hardly be due to a deliberate silence on this subject, and it is difficult to avoid the sinister interpretation that such syndromes probably do not exist and that the aspiration of any marked quantity of water into the lungs is fatal."

MILITARY OTOTOLOGY AND AVIATION MEDICINE

FRANK A. PERRI, *Lieutenant Colonel, USAF (MC)*

DURING 15 years as a physician with the Air Force, I have been impressed by the number of medical officers who are not fully aware of the important and close association of ear disease with military aviation medicine. Perhaps this is because many otolaryngologists are not flight surgeons and many flight surgeons have not made a special study of otolaryngology.

Both groups are faced repeatedly with otologic conditions that require immediate therapy in order to maintain trained crew personnel at peak performance. Many an otologic problem even seems to mean the end of the flying career of a highly proficient pilot, when in reality it is an easily repairable defect that should be only temporarily incapacitating. Conversely, there are minor conditions which can become irreversible and may well end a flying career if proper precautionary steps are not initiated immediately. Into another class fall the seemingly harmless diseases of the ears, nose, and throat which require that immediate steps be taken to remove crew members from flying status for the safety of all concerned.

BAROTITIS MEDIA

Barotitis media (aero-otitis media) is an acute inflammation of the mucosa of the middle ear caused by trauma to the mucosa from inequality of pressure in the middle ear and external auditory canal. If left untreated, the disease may progress to serious complications. Because of negative pressure in the middle ear, the blood vessels undergo rapid dilatation. Failure to ventilate the middle ear at this stage further results in an intense congestion of the tympanic membrane and an actual ecchymosis of the membrane and middle ear cavity. The membrane often ruptures when the pressure in the middle ear is rapidly reduced while the eustachian tube is closed. Prolonged negative pressure in the middle ear produces transudation of a yellow serosanguineous fluid into the middle ear cavity and the mastoid air cells. This transudate then becomes infected, leading in various cases to acute suppurative otitis media, acute or chronic suppurative or nonsuppurative mastoiditis, acute or chronic eustachian salpingitis, or destruction of the tympanic membrane with loss of hearing in the involved

From U. S. Air Force Hospital, Sampson Air Force Base, Geneva, N. Y. Col. Perri is now assigned to U. S. Air Force Hospital, Chanute Air Force Base, Rantoul, Ill.

ear. In clinical practice, all of these conditions have been seen as a result of untreated or insufficiently treated barotitis media.

The prevention of complications and the maintenance of crew personnel in constant flying readiness depends upon immediate and proper therapy. Crew personnel should be instructed in the early recognition of this condition, and should adopt prophylactic measures, as follows:

1. In the presence of acute inflammatory conditions of the upper respiratory tract, no matter how mild, crew personnel should not be permitted to fly.

2. When descending from high altitudes, the oxygen mask should be removed at altitudes of less than 10,000 feet. Personnel who have been breathing pure oxygen at high altitudes for a considerable period may develop ear distress from two to six hours after descent, particularly if oxygen is breathed until ground level is reached. This is caused by absorption of oxygen from the middle ear in the presence of eustachian tube obstruction.¹

3. Upon the onset of barotitis media during flight, ascent to a higher altitude should be made immediately, followed by a slow descent while attempting the Valsalva maneuver.

4. If the condition persists, crew personnel should report to the unit surgeon immediately after landing.

Diagnosis. When the condition has progressed until the middle ear is filled with fluid, diagnosis and therapy become major problems. The diagnosis can be made upon the history, by inspection of the tympanic membrane, and by insufflation of the middle ear if required. In the history, the patient will usually mention one or all of the following symptoms: loss of hearing or muffled hearing, fullness in affected ear, "water in ear," and tinnitus. The examiner usually sees a slight retraction and yellowish tinting of the tympanic membrane, with redness at the periphery of the membrane and along the handle of the malleus. A fluid level and/or bubbles of air may appear in the middle ear cavity. If the whole middle ear is filled with transudate, no fluid level will be seen and the middle ear must be insufflated in order to view air bubbles and establish the diagnosis.

Therapy. When transudate is not present, therapy consists of reducing congestion and pressure differences between the middle ear and the atmosphere. The first is done by applying a copious spray of a one-quarter of one per cent solution of Neo-Synephrine Hydrochloride (brand of phenylephrine hydrochloride) to the mucosa of each nasal fossa. A cotton-tipped metal applicator soaked in a 5 per cent solution of cocaine hydrochloride is applied to the orifice of the eustachian tube on the affected side for five minutes.

A eustachian tube cannula is then placed at the orifice of the tube, and air is introduced at a pressure of from 3 to 4 pounds. The Toynbee diagnostic tube that connects the ear of the patient to the ear of the flight surgeon indicates the instant that air reaches the middle ear, restoring its normal physiology.

When transudate is present, it must first be aspirated. A 3-inch-long, 22-gauge spinal needle with a short bevel, attached to a tuberculin syringe, is introduced into the middle ear through the most inferior posterior portion of the tympanic membrane, and the fluid is aspirated slowly. No anesthesia is required, as very little discomfort is experienced. The nasal mucosa is then constricted, the orifice of the eustachian tube cocaineized, and the middle ear insufflated as previously described, in order to remove any remaining transudate. This therapeutic procedure reduces the period of convalescence from 21 to 5 days. The perforation of the tympanic membrane is completely healed within 48 hours, and seldom is there a recurrence of the transudate after the pressure on both sides of the tympanic membrane has been equalized.¹

TRAUMATIC CENTRAL PERFORATIONS OF

TYMPANIC MEMBRANE

Central perforations of the tympanic membrane are distinguished from peripheral by the fact that the whole rim of the perforation is within the tissue substance of the membrane, inferior to Shrapnell's membrane, and not in contact with the bony annulus tympanicus. This type of perforation occurs in crew members during rapid descent in flight or in altitude chambers, and during and after acute infections of the nose and throat.

That traumatic central perforations do persist and often resist nature's efforts to heal them is all too manifest in the practice of clinical otology, but with adequate therapy, this need not occur. There also is no dispute that certain central perforations do produce a loss of hearing and subject the middle ear to a chronic suppurative infection followed by more severe complications; however, Adams² reported a series of cases in which there was successful healing of these perforations along with eventual return of hearing in the affected ear as proved by audiometric study.

If the examining physician finds that a central perforation of the tympanic membrane has not initiated its own healing process within 48 hours following trauma, the flight surgeon should then take the proper measures to close the perforation.

Therapy. The following therapy, which has proved successful in a number of our cases, is performed on an outpatient basis while the crew member is on a nonflying duty status:

After bilateral audiometric study, the whole rim of the perforation, plus a small portion of the outer surface adjacent to the rim, is touched with a small amount of very compact absorbent cotton that has been placed on the end of a copper applicator and moistened at the tip with 50 per cent trichloroacetic acid. This is repeated twice weekly, depending upon the membrane response, for at least eight weeks. In many instances there will be a rapid response to therapy, in which case the strength of the trichloroacetic acid is decreased and the solution applied only once each week. A second audiometric study is made after the perforation has healed.

BAROSINUSITIS

The paranasal sinuses present a condition in flight similar to that of the middle ear, except that their orifices, when not closed by mucosal congestion, are fully patent and rigid at all times. Mucosal congestion will prevent an exchange of air and pressure between the paranasal sinuses and nasal fossa during descent from altitude, with the result that pain in a sinus will be experienced because of the pressure inequality. Transudation and secondary infection may follow.

The flight surgeon can alleviate the discomfort and pain of barosinusitis by inserting a pledget of absorbent cotton soaked in 0.25 per cent Neo-Synephrine Hydrochloride in and around the middle meatus. The pledget is left in place for five minutes. If the condition is not relieved after this period, the procedure is repeated. After the second application, it will be noted that the nasal mucosa has reached maximum vasoconstriction, both nasal airways are patent, and the pain and discomfort have disappeared because the sinal pressure is atmospheric. A roentgenographic study is made in order to rule out pathologic conditions of the sinuses. The patient is then placed on a solution of 0.25 per cent Neo-Synephrine Hydrochloride solution and instructed to use 10 drops of the solution in each nostril while in the head-low (Proetz) position.

SUMMARY

The important role of ear disease in aviation medicine has not been sufficiently emphasized. Proper care and disposition of many aviation patients depend on thorough knowledge of diagnostic criteria, treatment, and prognosis of ear disorders.

Barotitis media may be diagnosed from the history, from inspection of the tympanic membrane, and by insufflation of the middle ear if necessary. If there is no transudate in the middle ear, therapy consists of reducing congestion at the nasal end of the eustachian tube and equalizing the pressure on the two sides of the tympanic membrane. If a transudate is present, these measures must be preceded by aspiration. If inadequately treated, barotitis may result in permanent hearing loss.

Traumatic central perforation of the tympanic membrane in my experience has healed most rapidly if treated with topical applications of 50 per cent trichloroacetic acid.

The paranasal sinuses may react to pressure changes in a manner similar to the middle ear, if their orifices are blocked by mucosal congestion. Barosinusitis responds well to treatment with topical vasoconstrictors.

These three seemingly minor otolaryngologic conditions may attain extreme importance when they occur in flying personnel. When not treated promptly and adequately, they cause the loss of highly trained personnel.

THE PHYSICIAN AS AN INDIVIDUAL

"It is axiomatic that treatment must be individual and will vary from patient to patient. But what is true of the patient is also true of the doctor. The resourceful physician presumably will not attempt to follow unquestioningly any fixed school of teaching. Medical education does not standardize the personality of the doctor. Each will and should have his own manner of dealing with patients, developing a flexible psychotherapeutic technique best suited to his own nature."

Journal*, p. 256, Feb. 15, 1956

DENTAL EXAMINATIONS OF 8,139 ARMY RECRUITS

Preliminary Report

ROBERT W. HOBSON, *Lieutenant Colonel, DC, USA*

PERIODICALLY, members of the U. S. Army Dental Corps have been asked by various organizations for information concerning the dental status of Army recruits. Prior to this study no compilation of information was available on which to base an adequate reply.

METHOD

Examinations were conducted in all of the six Army Areas during the months of April and May 1955. Every third enlisted man within the category of recruit or separatee who reported to the dental clinic was examined. By distributing the examination points throughout the United States and by examining every third individual within the specified time, sufficient randomness was obtained to give the results validity.

For the purpose of this study, a recruit was defined as "an inducted or enlisted man without prior military service." A separatee was defined as "an enlisted man who has completed not less than 20 and not more than 24 months of service."

Although the examination form used (fig. 1) admittedly has its limitations, it was considered desirable to employ a form from which all information could be transcribed to a single IBM punch card. The fact that spaces for recording are limited on such a card imposed a limitation on the number of questions that could be answered. Under part 8b, the clinical examination was to include bite-wing roentgenograms. In part 12 (prosthetics), the extractions needed as well as missing teeth and unserviceable dentures were to be reflected under the column headed "needed." The numbers in the columns in this part were for coding purposes only, and were to be disregarded by the examining officer.

This preliminary report includes only the recruits examined. No analysis has been made of the geographic distribution of this

group of individuals, or of their dental classification. The information derived from these two parts of the study will be reported at a later date.

Figure 1. Examination form for dental evaluation.

RESULTS

Of the 8,139 recruits examined (table 1), 7,889, or 97 per cent, were in the group aged 17 through 26 years. It is this age group that is of most interest, because selective service at present

draws mainly from the group aged 18 through 26. From table 1 it can be determined that the 7,889 recruits aged 17 to 26 years required 38,137 restorations involving 57,267 surfaces, or an average per man of 4.8 restorations involving 7.3 surfaces.

TABLE 1. *Restorations needed by 8,139 recruits*

Age	Number of recruits	Number of restorations needed	Number of surfaces	Average number of restorations needed	Average number of surfaces involved
16	4	20	24	5	6
17	879	5,446	7,642	6.20	10.15
18	1,410	7,119	10,688	5.05	7.25
19	1,604	7,022	11,229	4.68	7.64
20	1,442	7,225	11,118	5.01	7.75
21	985	4,906	7,137	4.98	7.28
22	486	2,187	3,249	4.50	6.72
23	372	1,388	2,038	3.73	5.50

30-48	37	131	200	3.54	5.41
Total	8,139	39,017	58,543	4.8	7.2

In the assessment of defective fillings (table 2), the examining officer was cautioned to count only those restorations where caries had reoccurred or the material had broken, badly washed, or loosened for some unknown cause. Even with these criteria, it was found that approximately one out of four recruits needed a defective restoration replaced.

The impossibility of rehabilitating patients dentally, with the present dentist-troop ratio, can readily be seen from table 3, which shows that for every four recruits, one bridge is needed.

The tremendous amount of time required for this type of treatment precludes its being rendered except when it is needed in the anterior portion of the mouth.

TABLE 2. *Defective fillings present on examination*

Age	Number of recruits	Number of defective fillings
16	4

Total	8,139	2,102

The number of missing teeth (table 4) per recruit is 3.93, and the number of extractions needed averages 0.8 per individual. This does not take into consideration extractions that may be required when operative procedures are attempted or when prosthetic work is started.

A reflection of this total (4.73 missing teeth, when extractions are completed) can be seen in table 5, which lists the dentures needed. The results of this examination show that for every 100 recruits, 19 dentures of all types are required.

Table 6 reveals that 22 per cent of the recruits were in need of periodontal treatment of some degree, and that 45 per cent were in need of a prophylaxis.

DISCUSSION

A review of the literature¹⁻⁵ along with personal correspondence was made in an attempt to arrive at the probable number of carious lesions per year in the recruits examined. The first large scale compilation that could be found was done by Hollan and Dunning,² who reported an annual increment of 1.75 carious surfaces per person. Klein⁶ found that in the young or college freshman age group, an annual increment of about 1.5 could be expected. Arnold, Dean, and Singleton⁷ found an annual increment of 2.2 new carious surfaces per year. Examination of a group of freshman college students in Des Moines, Io

In view of the preceding findings, I believe that 1.5 is a conservative estimate of the annual new caries rate for recruits in the Army. This would mean a total of 3 new lesions during the 2-year obligated period. Added to the average number of restorations needed on induction, it can be seen that the average young man of draft age, during his 2-year period in the Army, would require the insertion of 7.8 restorations if he were to be discharged in a caries-free condition.

SUMMARY

An examination of 8,139 recruits from all six Army Areas was conducted in order to determine the dental status of this group of young men. During a two-month period every third recruit reporting to the dental clinic was examined, and the results were recorded on a standard form.

For the average recruit, 4.8 restorations involving 7.2 surfaces were needed. One out of every four individuals needed a defective filling replaced, and one out of every four was in need of a bridge. The average recruit was missing 3.93 teeth with 0.8 extractions indicated. This did not include extractions needed for the construction of prosthetic appliances or where it was found impossible to render restorative treatment. For each 100 recruits, 19 dentures of all types were needed. Twenty-two per cent of all

patients examined had some degree of periodontal involvement, and 45 per cent were in need of a prophylaxis.

A review of the literature indicates that a caries expectant rate for each individual of 1.5 new lesions per year would be a conservative estimate. Coupled with the need for dental treatment observed in the average recruit, this means that during his two-year period in the Army, the average young man of draft age would require the insertion of a total of 7.6 restorations to discharge him in a caries-free condition.

"Nevertheless, in most cases of furring of the tongue the cause of the furring is probably to be found in one of three conditions: local infection, a dry mouth, or the irritant effect of tobacco smoke. Local infection may come from the mouth itself (as in stomatitis), or from the nose or throat (as in tonsillitis, colds, and sinusitis), or from the lungs (as in bronchitis and pneumonia). Dehydration of the mouth may result from a general state of dehydration, or from the dry mouth of a fever, or from blocked nose, and smoking presumably acts by the direct irritant action of tobacco smoke on the tongue."

MARITAL ADJUSTMENT PROBLEMS IN AN OVERSEAS THEATER

Psychiatric Implications

JOHN W. BURKETT, *Major, MC, USA*

THOSE who deal with emotional problems often need to be reminded that psychiatric patients cannot be considered as isolated cases or disease entities. They must be evaluated and understood in terms of their interpersonal relationships and of how their emotional difficulties affect not only themselves but others. To represent them as decompensations without reference to their current interpersonal relationships is of limited value in practical management.

Meaningful or positive interpersonal relationships such as close friendships, family ties, and good marital bonds constitute the foundation of mental health. They promote individual security and enable individuals to form group identities. Such factors are of recognized value in helping to sustain the soldier or officer in peace or combat. An impairment or paucity of such meaningful interpersonal relationships may result in loss of emotional support and consequent neurotic attempts to solve emotional problems.

The family life of both enlisted and officer personnel is often of primary importance in determining emotional adjustment. A careful evaluation of family life may reveal the dynamics of an otherwise obscure psychiatric disorder. It may be useful or even indispensable to interview and evaluate the wife and sometimes the children of the serviceman or officer with psychiatric symptoms. Conversely, when wives or children come to the psychiatrist for consultation, an evaluation of the emotional status of the husband is frequently indicated. The value of taking special note of current interpersonal relationships is well recognized by psychiatrists, but may be overlooked by other medical officers. Failure to take the patient's total current behavior into consideration often results in an inaccurate diagnosis and consequent improper management of the case.

This article emphasizes the need for taking all interpersonal relations of the patient into consideration, with special emphasis on marital adjustment, and points out the importance of this concept in an overseas theater, where marital problems appear to be more frequent than in the United States. It is believed that there was an actual increase in the more serious types of marital difficulties among military personnel in overseas theaters during the past few years, and the absence of the usual civilian physicians and ministers, to whom people with marital problems often turn, tended to increase the number of such cases encountered.

DISRUPTIVE FACTORS

Overseas service presents unique factors which one would expect to increase general family problems, in particular marital difficulties. The most obvious of these is the usually long separation of the husband from the family. The necessity for the entire family to adjust to a foreign culture that is obviously different in language and customs and subtly different in attitudes and philosophy also plays a causative role. The anxieties of being in a potential combat zone tend to be displaced onto other situations and to exercise an adverse effect on family life. Children are faced with the emotional stresses incident to changing schools and forming new friendships when they arrive overseas. In the younger children the absence of the father for a significant period of time almost always causes some emotional problems. The presence of relatively large numbers of unmarried women with a low standard of living increases the possibility of marital infidelity with its consequent detrimental effect on family life.

Many of the officers and noncommissioned officers who were sent overseas during 1951 and 1952 had been recalled from the reserves and were faced with their second major disruption of family life within a few years. The availability of domestic help tended in many instances to decrease positive activity and to create leisure time that housewives were not equipped to use constructively. Family life for the husband in the combat unit was even more difficult. His intensive field training resulted in frequent and prolonged separations from his family even after they arrived overseas.

It is probable that all these and many other factors were operative in creating unique problems which in many instances resulted in marital tensions. This does not imply that severe marital difficulties were universal, for in most instances these problems were met realistically and an adequate adjustment made.

LEGAL COMPLICATIONS

In cases of definite marital discord, legal and administrative red tape created additional problems. Legal separation was impossible, and return of the family to the United States might take

many months of endeavor. Temporary separation, which at times may help marital problems, was almost impossible. In a number of instances husbands who frankly admitted having girl friends continued to live with their families. This created an obviously impossible situation for the wife. She was put in the position of having either to report this situation to her husband's commanding officer or to attempt to ignore his conduct. Bringing the husband's actions to the attention of his commanding officer would probably result in disciplinary action in the form of a fine and thus result in a financial loss to the family. Attempting to ignore his conduct was rarely a satisfactory solution. The husband, if a noncommissioned officer, was usually reluctant to move out of his family quarters because it would result in forfeiture of his coveted permanent pass and seriously interfere with his romance.

ANALYSIS OF CASES

The frequency of marital adjustment problems is reflected in this study of 173 dependent wives who were seen for psychiatric evaluation at an Army hospital in the period June 1953 to June 1954. Of these, 31 had serious marital problems in which at least one partner contemplated divorce, the wife contemplated return to the United States, or the husband was openly unfaithful. None of these 31 wives were psychotic, but all gave indications of previous emotional instability, neurotic symptoms, or severe dependency needs.

Of the dependent wives evaluated there was a higher ratio of hospitalizations (18 out of 31) than normally occurs in psychiatric practice. This is probably due to the fact that outpatients were usually from the local area served by the hospital, while most of the hospitalized patients were transferred from other hospitals. Many of these patients had been treated unsuccessfully with various medications; often they had not confided in the medical officer who first saw them, nor had he asked them about their general life adjustment.

CASE REPORTS

The following cases illustrate the effects of severe marital problems.

Case 1. The 41-year-old wife of a Sergeant was admitted to the closed psychiatric ward because of sudden and complete amnesia. She stated that she did not remember her identity or any of her past life, and did not recognize her husband. Her husband stated that just prior to the onset of her symptoms she "became cold as ice and shook all over." When the husband was interviewed, he was at first guarded and stated that nothing unusual had happened recently and that he could think of no emotional disturbances in the home. With encouragement, however, he disclosed that two days prior to the onset of his wife's amnesia he had told her he wanted a divorce in order to marry a European girl. He

had previously hinted at his dissatisfaction with their marriage, and had made little effort to conceal his interest in the other woman. The patient had refused to discuss the problem with him.

During the interview, the husband frankly stated that he had fallen in love with the other woman and had no intention of trying to continue his marriage. He did, however, express some guilt in relation to his wife's illness and said that he would take no further action until she was well. Questioning revealed that he was influenced by the other woman's ability to make him feel important.

The patient's past history revealed a lifelong pattern of passivity, dependency, marked feelings of inferiority, and severe sexual conflicts. Although she had had no previous psychiatric hospitalizations, she had experienced a period of amnesia lasting several hours at the port of embarkation just prior to going overseas. It was subsequently learned that she had been uncertain about joining her husband because of his apparent indifference to her joining him, as reflected in his letters. She had previously been married, as had her present husband, and had three children by her first marriage. She married her present husband two years prior to his going overseas, largely because of economic insecurity.

She had complete amnesia and perplexity on admission to the hospital, but recalled all events following her entry. There was no indication of psychotic behavior or thought content.

During the first three days of her hospitalization she gradually recalled a few things about herself, among them her first marriage but not her present one. She also recalled some details of her early childhood. For several days she made no further progress despite daily psychotherapeutic interviews and strong suggestion. During intravenous administration of Amytal Sodium (brand of amobarbital sodium) she was able to recall all the details of her present marriage. This was accompanied by considerable emotional display. Following the interview she was tearful, depressed, and anxious. As she responded to psychotherapy, she was discharged and followed as an outpatient. She eventually was able to face her marital problem without recourse to neurotic symptoms.

Comment. This patient was a very dependent person who was unable to bear the thought that her husband wanted to divorce her, because it threatened her self-esteem and created feelings of helplessness. Her symptom of amnesia was clearly a rather poor defense against the anxiety that the conscious realization of her problem would create. Although the amnesia cleared after the administration of Amytal Sodium, it was followed by anxiety and depression.

Case 2. The 30-year-old wife of a Captain brought her 7-year-old son to the psychiatric clinic, stating that he complained of abdominal pain and was nauseated and irritable. He had been referred from the pediatric clinic after thorough evaluation failed to reveal any physical

cause for his complaints. He had been given various medications without improvement. Following her description of the child's behavior and symptoms she said that she herself had lost 31 pounds. She went on to say that the child complained most when she was upset and that she felt maybe she was more in need of help than the child was. She then suddenly stated that she was very upset lately because her husband was having an affair with a girl. Her husband had told her that he planned to retire overseas and live with the girl. She had been married eight years and believed that prior to her arrival a few months ago she had had no major marital difficulties.

She appeared to be a rather insecure, passive woman, but her previous emotional adjustment had been fairly good. She gave a history of severe tension-type headaches for many years. During the interview she cried a great deal and said that she did not want to leave her husband for fear of losing his financial support and of being unable to provide for herself and her child. Her husband had stated openly and definitely that he intended to continue his affair with the girl; however, he was reluctant to apply for his wife's return to the United States because he felt that it might adversely affect his Army career.

The child was pale and timid but not severely disturbed. It was clear that he was well aware of his parent's marital difficulties and was concerned about them. The mother was seen as an outpatient several more times and finally was able to go to her husband's commanding officer and discuss the entire problem with him. The child was not seen again, but the mother reported that he had become asymptomatic. The commanding officer said she could not go back to the United States without her husband's consent, but he impressed the husband with his duty to his family and the unreality of his present attitude toward his wife, and indicated that a modification of his attitude was desirable.

Comment. In this case, what appeared to be a pediatric problem was only part of a generally disturbed family situation. The mother was a very dependent person and totally unable to insist that her husband discontinue his affair with the girl. She clung to the fantasy that her marriage was a success and the present affair more the fault of the girl than of the husband.

Case 3. The 45-year-old wife of a Captain with 17 years' service was admitted to the psychiatric section after an apparent suicide attempt with a sedative. Her husband had found her unconscious on the steps of their home on the evening of admission. According to her husband, her behavior that day had not been unusual. She had served his dinner in the usual manner and then said that she was going for a walk with the dog. Just before leaving she took eight Seconal (brand of secobarbital sodium) capsules, which she previously had been given at another medical installation because of insomnia.

Interview with the husband revealed that during their 13 years of marriage there was little real affection between them, and that he had never considered the marriage a great success. He had, however, con-

had previously hinted at his dissatisfaction with their marriage, and had made little effort to conceal his interest in the other woman. The patient had refused to discuss the problem with him.

During the interview, the husband frankly stated that he had fallen in love with the other woman and had no intention of trying to continue his marriage. He did, however, express some guilt in relation to his wife's illness and said that he would take no further action until she was well. Questioning revealed that he was influenced by the other woman's ability to make him feel important.

The patient's past history revealed a lifelong pattern of passivity, dependency, marked feelings of inferiority, and severe sexual conflicts. Although she had had no previous psychiatric hospitalizations, she had experienced a period of amnesia lasting several hours at the port of embarkation just prior to going overseas. It was subsequently learned that she had been uncertain about joining her husband because of his apparent indifference to her joining him, as reflected in his letters. She had previously been married, as had her present husband, and had three children by her first marriage. She married her present husband two years prior to his going overseas, largely because of economic insecurity.

She had complete amnesia and perplexity on admission to the hospital, but recalled all events following her entry. There was no indication of psychotic behavior or thought content.

During the first three days of her hospitalization she gradually recalled a few things about herself, among them her first marriage but not her present one. She also recalled some details of her early childhood. For several days she made no further progress despite daily psychotherapeutic interviews and strong suggestion. During intravenous administration of Amytal Sodium (brand of amobarbital sodium) she was able to recall all the details of her present marriage. This was accompanied by considerable emotional display. Following the interview she was tearful, depressed, and anxious. As she responded to psychotherapy, she was discharged and followed as an outpatient. She eventually was able to face her marital problem without recourse to neurotic symptoms.

Comment. This patient was a very dependent person who was unable to bear the thought that her husband wanted to divorce her, because it threatened her self-esteem and created feelings of helplessness. Her symptom of amnesia was clearly a rather poor defense against the anxiety that the conscious realization of her problem would create. Although the amnesia cleared after the administration of Amytal Sodium, it was followed by anxiety and depression.

Case 2. The 30-year-old wife of a Captain brought her 7-year-old son to the psychiatric clinic, stating that he complained of abdominal pain and was nauseated and irritable. He had been referred from the pediatric clinic after thorough evaluation failed to reveal any physical

cause for his complaints. He had been given various medications without improvement. Following her description of the child's behavior and symptoms she said that she herself had lost 31 pounds. She went on to say that the child complained most when she was upset and that she felt maybe she was more in need of help than the child was. She then suddenly stated that she was very upset lately because her husband was having an affair with a girl. Her husband had told her that he planned to retire overseas and live with the girl. She had been married eight years and believed that prior to her arrival a few months ago she had had no major marital difficulties.

She appeared to be a rather insecure, passive woman, but her previous emotional adjustment had been fairly good. She gave a history of severe tension-type headaches for many years. During the interview she cried a great deal and said that she did not want to leave her husband for fear of losing his financial support and of being unable to provide for herself and her child. Her husband had stated openly and definitely that he intended to continue his affair with the girl; however, he was reluctant to apply for his wife's return to the United States because he felt that it might adversely affect his Army career.

The child was pale and timid but not severely disturbed. It was clear that he was well aware of his parent's marital difficulties and was concerned about them. The mother was seen as an outpatient several more times and finally was able to go to her husband's commanding officer and discuss the entire problem with him. The child was not seen again, but the mother reported that he had become asymptomatic. The commanding officer said she could not go back to the United States without her husband's consent, but he impressed the husband with his duty to his family and the unreality of his present attitude toward his wife, and indicated that a modification of his attitude was desirable.

Comment. In this case, what appeared to be a pediatric problem was only part of a generally disturbed family situation. The mother was a very dependent person and totally unable to insist that her husband discontinue his affair with the girl. She clung to the fantasy that her marriage was a success and the present affair more the fault of the girl than of the husband.

Case 3. The 45-year-old wife of a Captain with 17 years' service was admitted to the psychiatric section after an apparent suicide attempt with a sedative. Her husband had found her unconscious on the steps of their home on the evening of admission. According to her husband, her behavior that day had not been unusual. She had served his dinner in the usual manner and then said that she was going for a walk with the dog. Just before leaving she took eight Seconal (brand of secobarbital sodium) capsules, which she previously had been given at another medical installation because of insomnia.

Interview with the husband revealed that during their 13 years of marriage there was little real affection between them, and that he had never considered the marriage a great success. He had, however, con-

tinued to live with his wife since there were no actual quarrels or disagreements. Recently he had met a girl with whom he believed he was in love. Several weeks prior to his wife's suicide attempt he had openly stated that he no longer loved her and wanted her to return to the United States. She refused to do so, and he had continued to go out with the girl. During this time his wife suffered from insomnia and irritability. He realized that this was a rather unusual situation but felt that it was more convenient to live with his wife than move into the bachelor officer's quarters. One of his chief complaints about his wife was that she seldom gave him encouragement or support.

The patient's past history was characterized by chronic depression and several previous suicide attempts which had resulted in hospitalization. Her life had been rather colorless and she had few outside interests. There were no children, and neither she nor her husband particularly desired any. She felt, however, that hers had always been an "ideal marriage" and did not understand her husband's present attitude. She blamed the girl friend for her difficulties and expressed no overt hostility toward her husband. Although she was a licensed laboratory technician and had held a good position prior to joining her husband overseas, she was fearful about being without her husband's financial support. She had made no effort to seek legal advice regarding support in the event that she was divorced.

On entry to the hospital she was comatose, but completely recovered from the effects of the sedative after 24 hours. She was discharged after six days and followed as an outpatient. She was finally able to think about her future and past life more realistically and sought legal advice for her marital problem.

Comment. This patient's life had been characterized by denial of difficulties and repression of hostility. The marriage might have continued in much the same pattern if the husband had not gone overseas and found a woman who seemed to meet his needs.

DISCUSSION

Most of the cases presented a similar picture: a passive woman married to a relatively narcissistic man. The wife was unable to meet the neurotic needs of her husband. This did not lead to significant marital difficulties until the husband arrived overseas and met a woman who bolstered his self-esteem and at the same time satisfied his dependency needs. When this happened and the husband requested a divorce, the wife was totally unprepared to meet the situation in a realistic manner. In many instances the husband candidly admitted having a girl friend but continued to live under the same roof with his wife. This unrealistic and stressful situation was largely the result of the unique housing situation for dependents overseas. In all cases attempts were made to understand the personality characteristics and needs of both husband and wife, and to apply this knowledge toward improving their interpersonal relationships.

The large number of cases observed emphasized the extent of emotional disturbances in the dependent wives of servicemen and officers in an overseas theater. No attempt was made to include cases in which the marital problem was a minor one. In all these cases there was a serious marital problem, apparently directly related to the unique stresses of an overseas theater. All of the cases seen were of neurotic women whose marriages were only superficially stable or meaningful before their husbands went overseas. In those instances in which the husband deserted his wife for another woman primarily because of his own neurotic needs, he appeared to be more neurotic than the wife. It is believed that many of these marriages would have remained superficially stable had both partners remained in the United States. In some cases prompt legal separation or divorce probably would have decreased the emotional disturbance in the wife. A wife living in the same house as her husband and aware of her husband's interest in another woman is caught in an impossible situation.

The actual extent of marital problems is even more serious and widespread than would be suspected from the number of cases mentioned here. Many persons with marital problems resulting from the stresses of being overseas do not come to the attention of the psychiatrist but seek medical advice for various symptoms of anxiety. Some marital problems are never brought to the physician because of fear that the husband would be disciplined and the whole family suffer financial and other consequences.

CONCLUSIONS

The importance of recognizing and dealing with the emotionally disturbed patient in terms of his interpersonal relationships is often neglected. This is clearly illustrated by the number of patients with severe marital problems that go unrecognized because of failure to take the patient's total life situation into consideration. Such severe marital conflicts are more likely to occur in an overseas theater and are probably aggravated by some administrative policies. There are certain unique circumstances encountered by military personnel and their families overseas which adversely affect harmonious family life in general and marital adjustment in particular. It is suggested that efforts should be made to reduce some of the unique stresses in an overseas theater. The early recognition of such cases by medical officers might also help prevent the more serious types of emotional disturbance encountered.

SUMMARY

In one year, 173 dependent wives of servicemen were seen for psychiatric evaluation at an overseas Army hospital. Thirty-one of these patients had emotional disturbances resulting from serious marital problems.

During overseas service, unique disruptive factors increase family problems and marital difficulties in general. The medical officer must recognize the effect of these disruptive influences when evaluating emotional disturbances in military personnel overseas.

STRESS AND THE MILITARY

"Men with strong passive dependency drives who have functioned efficiently in combat and were promoted rapidly find it stressful, while separated from their families, to adapt to a peace-time Army routine involving assumption of full responsibility of grade in new units.

"Peace-time assignment of career soldiers to the locale in which they first were in combat can serve as a stressful element in persons who are not emotionally mature and who hold strong negative nationalistic prejudices."

Lethal Midline Granuloma and Periarteritis Nodosa

BYRON G. McKIBBEN, *Colonel, MC, USA*

MILWARD W. BAYLISS, *Colonel, MC, USA*

CASES of *granulomatous ulceration*, having their primary site in the midline tissues of the face, usually running an indolent course, even appearing to heal at times, but eventually ending fatally, occasionally have been reported in medical literature.¹ Similar cases of granuloma of unknown cause were reported as far back as 1906.²

Weinberg³ presented two cases of granuloma of unknown cause associated with *periarteritis nodosa*, in which he concluded that the vascular lesions were recent because there was no evidence of healing. He further stated that in all the cases of granuloma of obscure cause that were thoroughly studied and fully reported, *periarteritis nodosa* was a terminal development. In contrast to this, two of the cases adequately studied by Williams¹ failed to show the lesions of *periarteritis nodosa*.

Wegener⁴ described *periarteritis nodosa* as a common finding in patients with lethal granuloma. He believed that the condition causing the granuloma might also be the one causing the *periarteritis nodosa*. Gerlach⁵ described necrosis of arterioles at the site of the Arthus phenomenon. Williams stated that this observation had been confirmed repeatedly and therefore suggested that the same necrotic vascular reaction causing Arthus phenomenon when it involves capillaries is also responsible for *periarteritis nodosa* when it involves somewhat larger vessels.

Williams further concluded that one of the fundamental resistance mechanisms of the animal is a typical cellular immune response, primarily vascular, resulting in the Arthus phenomenon when capillaries are involved, producing a granuloma in deeper tissues or a *granulomatous ulceration* if skin and subcutaneous tissues are involved; that the *granulomatous ulceration* has a tendency to occur in the midline of the face, but is not confined to this location; and that there is a tendency for the involvement of the larger vessels (*periarteritis nodosa*) to occur in the end stages of the disease.

From Letterman Army Hospital, San Francisco, Calif. The authors are now assigned to the Tokyo Army Hospital, APO 500, San Francisco, Calif.

Kahn⁴ suggested that the reacting areas are sites of tissue hyperimmunity where antibodies formed from insoluble globulins are in excess. During later infections these areas of hyperimmunity extract specific or nonspecific antigens circulating in the blood and localize them with the production of the necrotizing and granulomatous vascular phenomena. He further suggested that allergic persons are the ones who develop these areas of hyperimmunity. This explains the development of the Arthus phenomenon when the body is invaded by bacteria which produce little or no toxin, and also explains the occurrence of this phenomenon in the absence of specific infection in a hyperimmune person, by the activation of highly immunized areas of tissue by nonspecific, nontoxic proteins gaining entrance to the blood stream. It has been shown that necrosin, which is either a euglobulin or is associated with this fraction in exudate and is liberated by injured cells, is a toxic substance capable of causing the central necrosis.⁷

The experimental work of Selye⁸ suggested a relative adrenal cortical dysfunction with excess production of the "salt-active" and relative suppression of the "sugar-active" corticoids. He found that excess sodium ion and an increased pH favor the development of periarteritis nodosa under experimental conditions, whereas elimination of sodium ion together with the giving of acidifying drugs tends to prevent its development. In 1949 Williams commented that the availability of hormones of the adrenal cortex would make possible new approaches to the study of granulomas.

Reports of cases of periarteritis nodosa responding favorably to cortisone or corticotropin began to appear in the medical literature;^{9,10} and some related disorders, such as lupus erythematosus disseminata,¹¹ asthma, and vasomotor rhinitis,¹² were showing improvement on such treatment.

With evidence pointing toward a relationship between idiopathic granuloma and periarteritis nodosa, Williams and Hochfilzer¹³ tried the effect of injections of cortisone on a patient in whom the diagnosis was idiopathic granuloma of the midline tissues of the face. While the course of the disease appeared to be altered somewhat favorably, they were of the opinion that cortisone would not prove to be a useful drug in the management of this condition, because of the slowness of healing and the unfavorable side effects, namely, interference with potassium metabolism and production of some general deterioration in the patient's condition.

In 1953 Hagans, Parry, and Markson¹⁴ reported a case of lethal granuloma of the nose and face treated with corticotropin which had remained healed 7 months. Follow-up, 22 February 1956, revealed that the patient had required no further treatment and

had remained entirely well.¹⁵ Full evaluation of this treatment however, awaits its use in more cases.

Early reports on the treatment of disseminated lupus erythematosus and polyarteritis nodosa with cortisone and corticotropin were optimistic, but it became apparent that the treatment was supportive only, and in no sense curative of the disease.¹⁶

Malkinson and Wells¹⁷ reviewed the therapeutic results of adrenal steroids on periarteritis nodosa and in conclusion stated that corticotropin and cortisone were the most effective agents for the treatment of this condition, despite serious disadvantages; that their use must be weighed carefully in each instance, and that one may expect the best results in a relatively young patient in whom treatment is started prior to the development of extensive visceral lesions and continued with proper dosage long enough for abatement of abnormal signs, symptoms, and laboratory findings.

The treatment of lethal midline granuloma remains obscure, and because of the rarity of this condition, it is not believed that a clear-cut regimen can be outlined in the near future. Until this condition is better understood, and in view of its apparent close causative relationship to periarteritis nodosa, it is suggested that measures which are found to be of value in the latter condition also be tried on lethal granuloma, and that when cortisone or corticotropin are prescribed, they be given in accordance with the principles suggested by Malkinson and Wells.

CASE REPORT

A 33-year-old white housewife was first seen in the ear, nose, and throat clinic of a U. S. Army hospital in Germany, 6 November 1952, with a complaint of difficulty in breathing through the left nostril. She stated that she had felt well until early October 1952, when she became aware of a slight nasal obstruction and pinkish color on her handkerchief after blowing her nose. She thought she had a cold and paid little attention to her symptoms.

Approximately five weeks before the onset of the nasal symptoms, she had noticed a small, tender nodule in each buttock, and one in the medial aspect of the left thigh. She had a cholecystectomy scar which was intermittently tender, and it was during a hospitalization for surgical revision of this scar and excision of the nodule in the thigh that she was seen by the otolaryngologist.

Past history and family history revealed that she had had one tubal pregnancy treated surgically. Two other pregnancies terminated in the birth of normal children. In 1946, she had a chronic cough for three months, followed by bronchial pneumonia. She was treated with sulfadiazine and was confined to her bed for 12 days. During the convalescent period she was troubled with pain in the right side of the chest posteriorly. Recovery was complete.

CASE REPORT

A 33-year-old white housewife was first seen in the ear, nose, and throat clinic of a U. S. Army hospital in Germany, 6 November 1952, with a complaint of difficulty in breathing through the left nostril. She stated that she had felt well until early October 1952, when she became aware of a slight nasal obstruction and pinkish color on her handkerchief after blowing her nose. She thought she had a cold and paid little attention to her symptoms.

Approximately five weeks before the onset of the nasal symptoms, she had noticed a small, tender nodule in each buttock, and one in the medial aspect of the left thigh. She had a cholecystectomy scar which was intermittently tender, and it was during a hospitalization for surgical revision of this scar and excision of the nodule in the thigh that she was seen by the otolaryngologist.

Past history and family history revealed that she had had one tubal pregnancy treated surgically. Two other pregnancies terminated in the birth of normal children. In 1946, she had a chronic cough for three months, followed by bronchial pneumonia. She was treated with sulfadiazine and was confined to her bed for 12 days. During the convalescent period she was troubled with pain in the right side of the chest posteriorly. Recovery was complete.

Examination of the nose on 6 November 1952 revealed an area of ulceration on the left side of the nasal septum and another on the medial surface of the anterior portion of the left inferior turbinate. The cardiolipin test for syphilis was negative. Complete blood cell count and urinalysis were normal.

On 7 November a tender nodule in the cholecystectomy scar and one in the left thigh were excised. Histologic examination showed large central areas of scarring granulation tissue with scattered microabscess-like features. Eosinophils were prominent and there were a few macrophages laden with brown and granular pigment. The diagnosis was granulomatous panniculitis (fig. 1).

Figure 1. Photomicrograph of section of the nodule from the buttock showing granulomatous panniculitis with infiltrate composed of lymphocytes, plasma cells, neutrophils, and eosinophils. The wall of the small arteriole in the center has a smudgy appearance due to fibrinoid degeneration. (Hematoxylin and eosin stain, $\times 100$)

On 14 November biopsy specimens were removed from the nasal lesions, which by that time had extended to the right nasal fossa. The tissue was soft, friable, and bled easily, and the nose was very tender and painful. Histologic examination showed acute and chronic inflammation (fig. 2). Cultures from this material showed a moderate growth of hemolytic *Micrococcus pyogenes* var. *aureus* (*Staphylococcus aureus*), *Micrococcus pyogenes* var. *albus* (*Staphylococcus albus*), and *Corynebacterium xerose*.

The patient had been noticing an increasing deafness and pain in the right ear. On 25 November, the right tympanic membrane perforated spontaneously, releasing sanguinopurulent material. The patient was admitted to the hospital the following day. Culture from the aural dis-

charge and from the right nostril showed a heavy growth of hemolytic *M. pyogenes* var. *aureus*, moderately sensitive to streptomycin sulfate and chlortetracycline hydrochloride (aureomycin). Cultures for yeast and fungi were negative. One gram of streptomycin sulfate was given daily from 28 November to 11 December, when, because the patient's condition had not improved, the dose was doubled. Both nasal cavities were almost completely closed and the ulcerated areas were surrounded with friable-appearing mucosa which bled easily. The pain in her ear became almost unbearable, and she was depressed and cried at times.

Figure 2. Nasal biopsy. Section showing acute and chronic inflammation with a dense infiltrate of neutrophils, eosinophils, lymphocytes, and plasma cells. (Hematoxylin and eosin stain, $\times 200$)

By 19 December she was showing a little improvement, the pain was less severe and she was allowed to return to her home for the holiday season. Streptomycin sulfate was discontinued and 500 mg of chlortetracycline hydrochloride, four times daily, was prescribed.

The patient's condition continued to improve until 19 January 1953, when her hearing again became poor and there was recurrence of pain in her ears and nose. Shortly after this, an area of swelling associated with severe pain developed below the left eye, and she was again admitted to the hospital.

At that time it was noted that she was having a great deal of difficulty in hearing, the masses in the buttocks had increased in size, the nasal lesions were more extensive, acute dacryocystitis had

developed on the left side, and she had lost 23 pounds since the onset of her illness. The swelling under the left eye became fluctuant and on 2 February it was incised and allowed to drain.

The patient was transferred to an Army general hospital, and on 10 February two large masses were removed from the right buttock and one from the left buttock. Histologic examination showed acute and chronic inflammatory infiltrate, including neutrophilic and eosinophilic polymorphonucleocytes, lymphocytes, plasma cells, monocytes, foam cells, and multinucleated foreign-body type giant cells. There were areas of necrotic foci, some of which were seen grossly as soft central areas. The fibrous stroma varied from a very cellular to hyaline structure. There was no evidence of epithelioid tubercle formation. During this hospitalization the white blood cell count had dropped to 3,200 per μ l on one occasion and to 4,300 on another, with a normal differential count. Hemoglobin was 9.8 g per 100 ml. Repeated cultures of secretions showed hemolytic *M. pyogenes* var. *aureus* sensitive to penicillin and chlortetracycline hydrochloride. The urine remained normal. Her record did not show treatment for anemia or leukopenia, and she was discharged from the hospital on 21 February 1953.

She was readmitted to the hospital on 4 March, complaining of pain in both ears and nose. Examination showed the right tympanic membrane to be perforated and there was bloody discharge. The left tympanic membrane was bulging. There was a small healing lesion in the left lower eyelid. The incision over the lacrimal sac was healed. There was a large perforation through the cartilaginous portion of the nasal septum. Tuning-fork tests indicated a marked conduction deafness. White blood cell count was again normal, red blood cell count was 3,840,000 per μ l, and the hemoglobin was 12.7 g per 100 ml. Tuberculosis of the nose was suspected, and the patient was transferred to an Army general hospital where the diagnosis was thought to be eosinophilic granuloma of the nose, paranasal sinuses, left nasolacrimal duct, ears and temporal bones, and subcutaneous tissues of the buttocks and thighs. She was evacuated to the United States, arriving at this hospital 14 April 1953, where she was admitted on the otolaryngology service.

Examination revealed a thin, chronically ill woman, moderately depressed and in obvious discomfort. The patient's entire room was filled with a putrid odor. Her blood pressure was 118/70 mm Hg. Her temperature was normal. She spoke with difficulty because of numerous small tender lesions in the mouth. A deep ulcer, with raised erythematous edges, was noted just below, and medial to, the left eye, which was held closed most of the time (fig. 3). The right tympanic membrane was lusterless. The left tympanic membrane was retracted and there was a foul discharge although a perforation was not seen. Hearing was greatly diminished and tuning-fork tests indicated bilateral conduction deafness. Both nasal passages were greatly diminished in size because of granulosomatous, ulcerating masses on all surfaces.

The septal perforation, previously mentioned, was noted. The lesions on the buttocks were still draining, and small tender subcutaneous masses were noted on both shoulders and on the anterior aspect of the right thigh. The liver was palpated three fingersbreadth below the costal margin and was tender. The spleen was palpated two fingersbreadth below the costal margin and was not tender.

Figure 3. Granulomatous ulceration of the face, apparently originating in the nasolacrimal tract. Autopsy demonstrated a sinus tract leading to an ethmoid cell.

A tentative diagnosis of lethal midline granuloma was made. This was concurred in by the otorhinolaryngology consultant who advised that the secondary infection be brought under control with adequate antibiotic therapy and that the patient be given a course of cortisone. The medical consultant, while agreeing that the condition could be one of the collagen diseases, strongly advised against cortisone because of the danger of causing a widespread dissemination of the infection. The surgical consultant said he had never seen anything quite like it and suggested that an anaerobic infection might be the cause.

Biopsy specimens revealed a granulomatous inflammation of undetermined cause in a nodule on the right thigh, acute and chronic inflammation of the nasal mucosa, and necrotic tissue in a specimen from the tongue.

Roentgenograms of the sinuses showed marked thickening of the mucous membrane of the right maxillary sinus and complete cloudiness of the left maxillary sinus. There was no evidence of pathologic change in the bones of the skull.

Culture from the nasal mucosa grew nonhemolytic *M. pyogenes* var. *aureus* sensitive to chlortetracycline hydrochloride, Terramycin (brand

of oxytetracycline), Chloromycetin (brand of chloramphenicol), and erythromycin. Smears and cultures for acid-fast bacilli were negative. Guinea pigs inoculated with material aspirated from the left maxillary sinus and obtained by biopsies of the nasal mucosa and a subcutaneous nodule died prematurely of causes other than tuberculosis.

Between 17 and 23 April the patient was given x-ray therapy: 450 r (in air) to an 8- by 11-cm frontal portal and an equal dose to a 10- by 10-cm left lateral portal, with no significant improvement.

Because of the widespread involvement, the patient was transferred to the medical service on 25 April for general care. She continued to be seen daily by a member of the otolaryngology service.

Five hundred milligrams of chloromycetin, four times daily, was prescribed, pending the result of sensitivity studies being made in Dr. Brainard's laboratory at the University of California.

On 29 April it was the consensus at a medical conference that there was some unknown abnormality in the patient's body defense mechanism that could possibly be a lethal midline granuloma, but that the most obvious treatable disease was the widespread micrococcus infection, which was thought to be secondary. Sensitivity tests, run at the University of California, revealed that the organism was highly sensitive to chlortetracycline hydrochloride and relatively insensitive to all other antibiotics tested. Treatment was therefore changed from Chloromycetin to chlortetracycline hydrochloride in the same dosage. A Levine tube was passed into the stomach for the administration of medications and feeding formula.

Repeated blood cultures showed no growth. By 3 May the patient was beginning to show slight improvement; the nodules on the neck and thighs appeared reduced slightly in size but the lesions about the nose and upper lip had extended somewhat. The next number of deep red purpura-like spots were noted on the aspect of both legs. The subcutaneous lesions, however, failed to improve. By 18 May, the purpuric lesions had begun to fade, liver and spleen were no longer palpable, her mouth was open and she was able to sit in a chair for short periods. By 30 May she could breathe some through her nose, and the wounds on her face appeared to be improved. On 11 June, it was noted that her weight had dropped to 7.8 g per 100 ml. She was, therefore, given transfusions of whole blood (500 ml each). She was still given chlortetracycline hydrochloride four times daily.

elevations, and a mild drop in blood pressure (90 to 100 mm Hg systolic and 64 to 72 diastolic).

On 25 June culture from a buttock wound was reported as showing *M. pyogenes* var. *aureus*, sensitive only to Chloromycetin and bacitracin, and pseudomonas resistant to all antibiotics tested. Hemorrhagic lesions developed on the back of the patient's left hand, and small vesicles were noted over the left forearm and anterior chest. The liver and spleen were again palpable. The patient was unable to tolerate Chloromycetin, and was started on 25 mg of cortisone every six hours and 1 gram of potassium chloride three times daily. Her course was rapidly downhill, with increasing hemorrhagic skin lesions, marked perspiration, temperature of 102°F, and generalized nervous twitchings, and she died 30 June.

Autopsy. Autopsy performed 10 hours after the patient's death revealed the following pathologic processes which had not been observed previously.*

1. Necrotizing panarteritis (periarteritis nodosa) involving vessels of the stomach, intestines, liver, kidneys, and bladder. There were a few arteries in the kidneys and one in the liver in which fibrosis suggested healed panarteritis (fig. 4).

Figure 4. Connective tissue of the liver containing partially healed lesion of periarteritis nodosa in a small artery. This artery is practically obliterated by scar tissue while only a few inflammatory cells and a slight amount of fibrinoid material remain. (Hematoxylin and eosin stain, $\times 100$)

*Gross and microscopic examination was performed by Captain Joseph H. Masters, and the slides were reviewed by Dr. Alvin J. Cox, Major T. R. Anderson, and one of us (M. W. B.).

7. Blood culture (heart) revealed hemolytic *M. pyogenes* var. *aureus*, coagulase-positive.

COMMENT

It is interesting to note that there was some evidence of healed panarteritis in the kidneys and liver. Although the main picture was one of extensive inflammation and necrosis, there were a few fibrosed arteries, lacking in inflammatory cells, suggesting focal areas of healing or healed panarteritis. While periarteritis nodosa has been considered to be a terminal development in cases of idiopathic granuloma,^{1,2} this observation indicates that some of the vascular lesions had developed in an earlier stage of the disease.

SUMMARY

A case of lethal midline granuloma associated with periarteritis nodosa is presented. While periarteritis nodosa tends to be a terminal development in cases of idiopathic granuloma, the finding of a few focal areas of healed panarteritis in this case is evidence that these healed lesions, at least, developed during an earlier stage of the disease.

The two conditions (lethal midline granuloma and periarteritis nodosa) appear to be the result of hyperimmunity, causing the granulomatous lesions when capillaries are involved and periarteritis nodosa when somewhat larger vessels are involved.

Cortisone or corticotropin, in order to be of any benefit in the treatment of lethal granuloma or periarteritis nodosa, should be given early in the course of the disease, in adequate dosage and with careful supervision.

EVALUATION OF DISCOID LUPUS

"The classification of lupus erythematosus is an arbitrary one. There are many transitions between the types. Discoid lupus, from its inception, is a systemic disorder which is a variant of the more malignant acute disseminated form. The "benign"-appearing cutaneous lesion may be a herald of advanced systemic manifestations which may be present at the same time or at a later date, when the skin changes have healed. Therefore, all these patients should have a thorough general medical survey. The form of therapy instituted depends entirely upon the extent of the disease."

Placenta Accreta

JOHN R. O'BRIEN, M. D.

CHARLES C. SORENSON, Major, USAF (MC)

GORDON W. SCOTT, Captain, USAF (MC)

FREDERICK SILVERMAN, Captain, USAF (MC)

PLACENTA ACCRETA is "an abnormal adherence of part of the placenta or all of it to the uterine wall with partial or complete absence of the decidua basalis, especially the spongiosum layer."¹ Based on the depth of invasion of trophoblastic elements, Kallreider² classified the condition as: (1) placenta accreta (pathologic adherence only), (2) placenta increta (penetration of uterine wall), and (3) placenta percreta (uterine wall penetrated to or through serosal layer, and in some cases ruptured). A second classification describes the surface extent of the abnormal placental attachment: focal, partial, or complete.³

The main causal factor appears to be injury to the endometrium by trauma, infection, an associated obstetric or gynecologic disorder, or an endocrine imbalance. Traumatic causes include previous manual removal of an adherent placenta leaving scars, dilatation and curettage, therapeutic abortion, radium therapy, and cesarean section. Infections include tuberculous peritonitis and endometritis. Fibroids, diverticula, placenta praevia, cornual implantation, placenta membranacea, and adenomyosis have been listed as associated obstetric or gynecologic disorders. A defective corpus luteum might contribute to an endocrine imbalance leading to placenta accreta.^{4,5,6}

Various estimates as to incidence range from 1:1956 (Irving and Hertig⁷) to 1:25,000 (Chern and Rosenberg⁸). Greenhill⁴ believed it to be 1:2,000; Chisholm,⁹ from 1:200 to 1:20,000; and Phanouf⁶ found an occurrence of 1:14,622 in his survey. Eastman⁵ did not observe a single case of complete accreta in over 70,000 deliveries. Only a few more than 200 cases were recorded up to 1953.¹ Israel, Siegel, and Rubenstone¹⁰ stated that a total of 31 cases of simultaneous placenta praevia and accreta had been recorded in the literature up to 1955.

Clinically, there is only a failure to expel the placenta normally. Normal separation from areas totally lacking in decidua is impossible. With complete accreta no bleeding is present because all of the placenta is adherent. Some retained placentae

may be focal placenta accretae, with multiple fibrous attachments to the uterus. Partial accreta is often accompanied by the severe bleeding associated with partial separation. In rare instances, hemorrhagic shock may be associated with spontaneous rupture of the uterus and/or trophoblastic erosion of large uterine artery branches, leading to massive intra-abdominal hemorrhage. Other factors which may cause hemorrhage are placenta praevia, traumatic attempts at manual removal leading to rupture of the uterus, rupture by a curet, or inversion of the uterus.^{1,9,11} Diagnosis is made by failure to find a cleavage line in attempting atraumatic manual removal of the placenta.

The treatment of choice for almost all patients is listed in standard texts as immediate abdominal hysterectomy once the diagnosis is made.^{1,9,12} Muir¹ reported a case in which the placenta of a four and one-half month abortus could not be removed manually. There being virtually no bleeding, the patient was put to bed and given antibiotics. By eight weeks, uterine drainage had ceased. Two months later the patient became pregnant, going on to a normal delivery and third stage. Greenhill¹ cited 14 cases in which the placenta was allowed to remain intact without an attempt at removal. All 14 women survived. Others⁴⁻⁶ urge conservative treatment when possible. It is recommended that the therapy chosen should depend on the amount of bleeding and the uterine response to complete or partial removal of the placenta. In complete accreta with little bleeding, the placenta should be drained of fetal blood and allowed to become organized and absorbed. With partial accreta too densely adherent to be removed, the uterus should be packed and treated expectantly. Unfortunately, even with adequate blood replacement this rarely suffices, and hysterectomy becomes the treatment of necessity. Israel, Siegel, and Rubenstone recommended that with combined placenta praevia-placenta accreta discovered at cesarean section, hysterectomy be done. The following case report describes an attempt at conservative therapy for partial accreta which failed, and for which hysterectomy was necessary.

CASE REPORT

A 26-year-old woman, gravida 2, para 1, whose estimated date of confinement was 30 June 1955, was admitted to the maternity ward of this hospital at 2100 on 10 July with a history of cramping pain in the lower abdomen of several hours' duration. The pain ceased soon after admission. The patient was discharged the following morning, to be seen shortly in the prenatal clinic. She was readmitted on 14 July at 2300, with the bag of waters having ruptured earlier at home.

The prenatal course was marked by a moderate degree of polyhydramnios and a marked diastasis recti abdominis. Blood pressure determinations and repeated urinalyses were always within normal limits.

Hematocrit on 7 July (one week prior to delivery) was 38 ml per 100 ml, with a hemoglobin of 12 g per 100 ml. A roentgenogram of the abdomen taken on 7 July revealed a single fetus, near term, in cephalic presentation, with an unusually large amount of fluid present.

The previous obstetric history was that of one previous pregnancy in 1954, highlighted by mild post-partum atony of the uterus, and death of the 7 lb 7½ oz newborn infant 32 hours after birth due to massive intracranial hemorrhage, secondary to a right tentorial laceration.

Uterine contractions began at 0200 on 15 July. The first stage of labor ended at 0600. A saddle block anesthesia, using 3 mg of Pontocaine (brand of tetracaine hydrochloride) was performed at 0610. However, it was concluded shortly thereafter that the patient was not ready for delivery. She was returned to the first-stage room to be kept under close observation. Fetal heart tones remained good, as did maternal pulse and blood pressure.

At about 0945, a posteroanterior and left lateral roentgenogram of the abdomen and pelvis were taken showing the fetus in right occiput transverse position at +2 station.

At 1015, 4 hours and 15 minutes of the second stage having elapsed since the saddle block anesthesia, the patient was returned to the delivery room. Blood was drawn for typing and cross-matching. An infusion of 5 per cent dextrose in water was started. Penicillin and streptomycin sulfate were administered intramuscularly. The blood pressure at 1015 was 94/50 mm Hg. The patient was prepared, draped, and catheterized, and anesthetized with a pudendal block using 1 per cent Xylocaine (brand of lidocaine hydrochloride). At 1035, 75 mg of Demerol (brand of meperidine hydrochloride) were given intramuscularly, putting the patient to sleep.

Manual rotation of the head was unsuccessful, as was the use of Simpson's forceps via the wandering technic. The patient was delivered with Kielland's forceps, using the inversion method of application, of an 8 lb 10 oz male infant. The baby was in fair condition. Normal respiration was established in approximately 40 seconds.

The mother was given a 1 ml-ampule of Pitocin (brand of oxytocin) intramuscularly after delivery, at 1127. A transfusion of blood (500 ml) was started at 1134. Blood pressure at this time was 108/70 mm Hg and the pulse 84. One hour of the third stage elapsed without spontaneous delivery of the placenta, prior to an attempt at manual removal. A portion of the placenta was removed piecemeal. It was impossible to find a line of cleavage for all of the placenta. One milliliter of Ergotrate (brand of ergonovine maleate) was given intravenously. A 6-cm cervical laceration of the anterior lip was repaired. At 1245 blood pressure was 90/60 mm Hg and the pulse 92. By 1410, 1,000 ml of whole blood and 500 ml of dextran had been administered. Excessive bleeding, after repair of the cervical laceration, was encountered and

felt to be due in large measure to uterine atony. The uterus was thoroughly packed in what proved to be an unsuccessful effort to treat the atony.

At 1500, the patient was taken to the operating room. The packing was removed, the uterus re-explored, and the diagnosis of placenta accreta was confirmed. In view of the marked uterine atony, with consequent extensive bleeding, a rapid total hysterectomy was performed under general anesthesia. Blood was replaced in adequate quantities. The patient left the operating room with a pulse of 84, and a blood pressure of 110/84 mm Hg.

On opening the specimen, an 8- by 8-cm portion of placenta was noted to be tightly adherent to the anterior wall of the uterus. A 2-cm laceration was present at the left lateral aspect of the lower uterine segment. The cervical laceration had been entirely repaired.

Postoperatively, the blood pressure and pulse were maintained within normal limits. Therapy included adequate fluid and electrolyte replacement, massive doses of antibiotics, and multiple blood transfusions. The patient received a total of 3,500 ml of whole blood during her hospital stay. Spiking temperatures were present until the fifth postoperative day. The patient was discharged on the tenth postoperative day in good condition.

The pathology report by William A. Meriwether, Captain, MC, USA (6th Army Area Medical Laboratory, Fort Baker, Calif.) and confirmed by the Armed Forces Institute of Pathology noted grossly an area of undetachable placenta adherent to the uterine wall. Microscopically, "cotyledons were lying adjacent to the uterine musculature, separated only by an occasional decidual cell" (figs. 1-3).

Final diagnosis: Placenta accreta, partial.

COMMENTS

As previously noted, conservative therapy for partial placenta accreta is rarely successful. The occasional success, however, warrants a trial in young women of low parity, provided the patient is closely observed and adequate blood replacement is at hand.

In the case reported, the uterine atony encountered was apparently due to a combination of factors, namely, overdistention of the uterus, a greatly prolonged second stage, too vigorous attempts at manual removal of the placenta, and possibly, the rent in the lower uterine segment. A previous obstetric history of traumatic delivery and post-partum atony indicated the need for cautious management of the second and third stages of labor.

Figure 1. Low power view of cotyledons lying adjacent to uterine musculature. ($\times 100$)

Figure 2. Medium power view of villi adjacent to uterine musculature. ($\times 430$)

Figure 3. High power view of villi adjacent to uterine musculature separated only by an occasional decidual cell.

SUMMARY

A reported case of partial placenta accreta illustrates the fact that this condition usually warrants hysterectomy, total hysterectomy being the treatment of choice.

THE CASE FOR HYSTERECTOMY

When the health of a woman, physically and emotionally, is compromised by an abnormal uterus to a serious degree (and the judgment of this degree of disability is squarely on the shoulders of the conscientious surgeon performing hysterectomy), excision has proved one of the most satisfactory procedures in all surgery. The emotional confusion in consideration of the sexual organs, femininity, and procreation has prevented some from seeing or realizing the great importance of extending hysterectomy to those in dire need of it. Hysterectomy should never be performed for minor complaints and minor findings, but only when there are major diseases or when those complaints and findings add up to a major disability.

p. 500, Oct. 1954

Spinal Cord Pseudotumor

A Complication of Pantopaque Myelography

SARKIS S. SARKISIAN, *Commander, MC, USN*

WHEN radiopaque substances are injected into the spinal canal in myelography, an occasional local tissue reaction should be expected. Such a reaction was seen in a patient who had been evaluated for spinal cord tumor.

CASE REPORT

A 39-year-old woman had first noted urinary stress incontinence following an episode of viral pneumonia. This symptom gradually became worse, and on 4 January 1956 a myelogram was done, using Pantopaque (brand of iophendylate). This was repeated on 2 February. No tumor was revealed by either of these examinations.

On 29 February the patient noted the onset of numbness over the sole of the left foot, in the perineum, and along the back of the left leg. The physical examination and past history supplied no other pertinent information. The neurologic examination showed slight hypalgesia of S3, S4, and S5 segments. The impression was: cauda equina lesion with cord compression. A third myelogram on 15 March was interpreted as showing a tumor at the L5-S1 level. The filling defect measured 1 by 3/4 cm and was constant, suggesting a spinal cord tumor in this area (fig. 1).

On 21 March a laminectomy of L5, S1, and S2 was performed. This revealed an inflammatory subdural tumor mass, as much as possible of which was removed. There was an uneventful recovery, and one month postoperatively the patient was much improved. The tumor (fig. 2) was a lipoid granuloma composed of fibroblastic cell proliferation, foreign-body-type giant cells, and "punched-out" areas representing lipoid material.

DISCUSSION

Before Pantopaque was first used in clinical trials, Steinhausen and associates¹ studied its effects on dogs. They reported foreign body response when the oil was injected intrathecally, with encystment within about six weeks. When used in humans, Pantopaque has given excellent results generally. Marcovich, Walker, and Jessico² reviewed 150 cases in which iodized oil had been

used to examine the spinal cord and found no deaths referable to the injection. Bering¹ reported on a series of 106 cases in which he used Pantopaque with no untoward results, except for a single case where the Pantopaque became fixed in one mass. Arbunkle, Sheldon, and Pudenz² and Peachner and Robertson³ reported over 400 additional cases with no unusual findings.

Figure 1. Roentgenograms revealing constant filling defect at L5 and S1 level.

On the other hand, Camp⁴ reported encystment of Pantopaque subsequent to myelography. Luce, Leith, and Burrage⁵ described two cases of delayed noninfectious meningitis with spinal fluid findings of increased protein and inflammatory cells. Erickson and van Baaren⁶ reported a case presenting manifestations of late meningeal reaction with fatal termination, in which autopsy revealed a fibrinous exudate over the base of the brain and thoracic spinal cord, with microscopic evidence of widespread dispersion of oil.

Fine emulsification of the oil may introduce an additional hazard that must be considered during myelography. In fact, Jaeger⁷ showed that in dogs intrathecal injection of emulsified Pantopaque caused death in 10 minutes. It would seem that a bloody tap should be considered a contraindication for the injection of oil intrathecally, for blood can cause emulsification of the oil.

Figure 2. Photomicrograph of section of spinal cord lesion revealing typical lipoid granuloma. ($\times 200$) (Medical Illustration Section, First Army Area Medical Laboratory)

CONCLUSIONS

It is necessary to take precautions during any myelographic procedure when a foreign material is injected intrathecally. Injection of oil should be postponed in case of a bloody spinal tap. The iodized oil should not be emulsified with spinal fluid or other material. An attempt to remove as much of the iodized material as possible should be accomplished after completion of myelography. It should be remembered that injection of such materials can elicit local tissue proliferation as well as a systemic sensitivity response.

TEACHERS OF MEDICINE

"One of the diseases of our society is this erroneous belief that the brave new world will come to pass by miracles of structural design and intricate organization alone. Plans there must be, but personalities must take precedence of plans. The basic essential is to ensure that medical students, both undergraduates and post-graduates, are associated with (not just taught by) those whose lives and work are examples of excellence in scholarship and professional skill. These teachers must be ever dissatisfied with their efforts, critical of themselves and others, forever scheming and striving to test the truth of what appears to be known, and planning to enlarge knowledge. Among such there is no room for the complacent, the arrogant, the staunch upholder of tradition, and the stout defender of the status quo. The quality of our teachers is all-important and a heavy responsibility rests on those who have to select the academic staffs and consultants responsible for medical education."

—W. MELVILLE ARNOTT, M. D.
in *Lancet*, p. 785, Oct. 15, 1955

A MESSAGE FROM THE A. M. A.

No project initiated by the American Medical Association in the past 10 years has received wider applause and support than its program of assistance to medical schools in financing their operations. The American Medical Education Foundation was established in 1950 to stimulate voluntary contributions from physicians for use in support of the nation's approved medical schools.

Following World War II, the medical schools faced an expanded enrollment and mounting operating costs. Their teaching programs had to keep pace with the rapid advance of medical science and the broadening concept of medicine's role in the community. The traditional sources of income were insufficient to meet the postwar rising costs and at the same time maintain the high standard of medical education in the United States. It was estimated that at least an additional \$10,000,000 each year was necessary to make up the deficits of the medical schools.

To meet this need, the A. M. A. sponsored the American Medical Education Foundation, which was incorporated to receive donations from individual physicians to help defray the costs of our present-day medical education system and to administer the allocation of these funds. The A. M. A. gave \$500,000, the first donation to the Foundation, and agreed to finance the costs of promotion and administration. As a result, the Foundation is one of the few organizations now raising funds in the United States whose *entire income in contributions goes to the cause for which funds are donated.*

During the past six years, the Foundation has received and distributed \$4,684,312 to medical schools. In 1955, more than 25,000 contributors made individual gifts to the Foundation. The A. M. A. has made grants totaling \$1,100,000, which the Foundation has distributed for the private support of medical schools. It has continued to pay all administrative costs, and exerts every effort to encourage and further the program.

Several policies were established by the Foundation with respect to contributions, one of them being a rule that no donations would be restricted as to use in the medical schools. This policy was necessary since many restricted grants made in prior

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.
—Editor

years could not properly be integrated into a medical school's program because of the limited administrative and housekeeping facilities of the school. Many deans have expressed their gratitude for this rule that permits freedom of utilization and thereby makes the actual grant worth many times its face value.

Another policy adopted early was the acceptance from physicians of donations specifically earmarked for the school of their choice. This was done so that full expression could be made of the physician's loyalty to his alma mater. The rule also permits the Foundation to co-ordinate its efforts with an active annual alumni giving program. Since 1953 the Foundation has served the medical schools as a clearing house for statistical information in regard to alumni giving. It has reported each year the amount of money given without restrictions directly to each of the medical schools by their alumni.

The success of the American Medical Education Foundation has largely been a result of the work done by physicians in the constituent and component societies of the A. M. A. Across the nation, state associations have appointed chairmen and committees who have made it their job to tell their colleagues about the importance of support for the medical schools. In the American way, each state has adopted a different attack to this problem. A number of state medical societies increased the dues of individual physicians and allocated the increase to the Foundation. Other state societies have a voluntary entry for the Foundation on their dues statement, and many of the societies give large donations from their state treasuries.

These generous contributions from the societies themselves are matched in many states by purely voluntary appeals made in an organized way at the local level. The importance of the program, however, does not reach everyone's ears at once; so it has been a steady effort in education to acquaint every member of the profession with the existence of the Foundation and its purposes. It is expected that within a short time, the \$2,000,000-a-year goal from the physicians of the nation will be reached.

One of the questions constantly asked is how this money is used. Unsought replies to this question pour in from the medical schools. Deans constantly write in gratitude to the Foundation, describing the importance of this source of income. One medical school dean was able to raise the salaries of his instructors enough to show them that the school was appreciative of their services and thus hold his faculty, whereas he had been in danger of losing them because he had no other source of income for these raises. Another dean reported that it would have been impossible for him to increase the seating capacity of several classrooms if it had not been for grants received from this source.

As the costs of everything spiral these days, and a greater teaching burden is placed upon the medical schools by the expansion of medical knowledge, the support of the 82 medical schools of this country as they have always been supported, by the generosity of private philanthropy, must be continued. The nation's physicians must lead the way.

DEATHS

HALE, Legan Owsley, Major, DC, AUS, of Big Clifty, Ky.; stationed at Fort Jackson, S. C.; graduated in 1946 from University of Louisville School of Dentistry, Louisville, Ky.; appointed First Lieutenant 10 May 1949 and called to active duty 25 May 1949; died 29 June 1956, age 37, at U. S. Army Hospital, Fort Jackson, S. C., of bilateral pneumonia with complications.

McCULLEY, Grace Elizabeth, Lieutenant Colonel, ANC, USAR, of Trenton, N. J.; stationed at U. S. Army Hospital, Fort Carson, Colo.; graduated in 1929 from Newark City Hospital School of Nursing, Newark, N. J.; appointed Second Lieutenant, ANC, 8 July 1942; died 2 July 1956, age 50, at U. S. Army Hospital, Fort Huachuca, Ariz., of hypertensive cardiovascular disease.

NEW NAVAL HOSPITAL IN CUBA

The new 100-bed U. S. Naval Hospital at Guantanamo Bay, Cuba, was dedicated on 28 September 1956. The hospital cost \$2,500,000 exclusive of equipment, and is the first naval hospital to be completely air conditioned. It will replace the temporary building used for many years as the base hospital.

Among the distinguished guests present was Dr. F. B. Berry, Assistant Secretary of Defense (Health and Medical). During the ceremony Rear Admiral B. W. Hogan, Surgeon General, U. S. Navy, accepted the new structure with its latest medical facilities and then turned it over to Captain L. A. Newton, MC, USN, Commanding Officer. In dedicating the hospital the Surgeon General paid tribute to the men and women of the Medical Department of the Navy, saying:

"Here, again, we find—and I am most happy to remark on it—that this grand record in hospitalization in Cuba is due very largely to the magnificent examples of those medical men and women of the Navy who have here preceded us—their examples of love for the Navy, of zeal to advance themselves constantly in knowledge and proficiency, and of devotion to their duties—their example, which is possibly the most to their credit, of kindly consideration and encouragement for their patients.

"It is an anatomical fact, that the heart is halfway between the head and the hand. At the bedside of a sick or wounded bluejacket, the brainy mind of the doctor is very important; as, likewise, the deft and sensitive hand that holds the scalpel is a blessing to the patient, of

Dedicatory address is presented by Rear Admiral Bartholomew W. Hogan, MC, USN, Surgeon General, U. S. Navy. Seated, left to right, are Captain Willard C. Calkins, MSC, USN, Director, Medical Service Corps Division, Bureau of Medicine and Surgery, Department of the Navy; Captain Leslie D. Ekvall, MC, USN, District Medical Officer, 10th Naval District; Captain Lyle A. Newton, MC, USN, Commanding Officer, U. S. Naval Hospital, Guantanamo Bay, Cuba; Doctor Frank B. Berry, Assistant Secretary of Defense (Health and Medical); and Rear Admiral William G. Cooper, USN, Commander, U. S. Naval Base, Guantanamo Bay, Cuba.

vital and paramount value. Above these boons, however, is the supreme Godsend of a kindly heart, the balsam of a cordial smile, the reanimating transfusion the physician gives by his sincere and personal interest in his each and every patient. By passing from hand to hand such a torch of medical excellence, even better in the future than in the past, our Naval Medical Department will one day see fully realized, if not all, at least the majority of the zealous and onward aspirations that now signalize it. . . . I hereby dedicate this hospital to the physical, mental, and spiritual welfare of all military personnel and their dependents. It is furthermore dedicated to all mankind in times of possible disaster."

THE NATIONAL LIBRARY OF MEDICINE

The Armed Forces Medical Library was transferred to the Public Health Service of the U. S. Department of Health, Education, and Welfare on 1 October 1957. The National Library of Medicine Act, signed by President Eisenhower on 3 August 1956, established a National Library of Medicine in the Public Health Service "to assist the advancement of medical and related sciences and to aid the dissemination and exchange of scientific and other information important to the progress of medicine and to public health." The Armed Forces Medical Library forms the nucleus of the National Library.

The Armed Forces Medical Library was founded in 1836 as the Library of the Surgeon General's Office, U. S. Army. It was one of the largest and most important medical libraries in the world. It contained almost a million volumes, representing literature on medicine, dentistry, pharmacy, and allied sciences in all languages and of all times. Its books were loaned to other libraries throughout the United States.

In administering the National Library of Medicine, the Surgeon General of the Public Health Service will be assisted by a Board of Regents consisting of 10 persons to be appointed by the President and confirmed by the Senate. Ex officio members of the Board are the Surgeons General of the Public Health Service, the Army, Navy, and Air Force; the Chief Medical Director of the Department of Medicine and Surgery of the Veterans' Administration; the Assistant Director for Biological and Medical Sciences of the National Science Foundation; and the Librarian of Congress. Colonel Frank B. Rogers, who was the Director of the Armed Forces Medical Library, is the Director of the National Library of Medicine.

The National Library of Medicine Act also authorizes the construction of adequate facilities to house the Library on a site to be selected by the Surgeon General of the Public Health Service at the direction of the Board of Regents.

Reviews of Recent Books

UNITED STATES ARMY IN WORLD WAR II. The Technical Services. The Medical Department: Hospitalization and Evacuation, Zone of Interior, by *Clarence McKittrick Smith*. 503 pages; illustrated. Prepared by the Office of the Chief of Military History, Department of the Army, Washington, D. C., 1956. For sale by the Superintendent of Documents, Government Printing Office, Washington, D. C. Price \$4.

This volume contains a detailed and lucid analysis of the complex problems that faced The Surgeon General in his efforts to administer the hospitalization and evacuation system of the Army in the Zone of Interior during World War II. Thus the problems dealt with are those of medical administration and logistics rather than those of clinical care. They were problems partly of his own making, but were in large part an inevitable corollary of those faced by a military organization—catapulted suddenly to 8 million strong—fighting a global war.

The narrative reflects the broad historical pattern of all the elements of the fighting organization in World War II: the initial unpreparedness—the early period of improvisation followed by attempts to clarify and standardize procedures—and the evolution of new policies and procedures to meet the changing requirements of global warfare.

The discussion is directed solely toward plans, policies, and operations at the level of Surgeon General of the Army, and the narrative "written from his vantage point." A delimitation of scope is necessary, but two observations are pertinent. First, this precludes any account of the viewpoint of the patient—1 individual out of a potential 8 million—caught up in the vast and impersonal "system" designed to maintain combat effectiveness. The reader misses the human element. Second, this delimitation has precluded more than an over-simplified statement of facts about situations peripheral to the Surgeon General's Office. For example, the bare statement that the Air Staff "remained nonetheless unconvinced of the wisdom or desirability of pressing for separate air forces hospitals generally" (p. 175), even in context, does not do justice to a complicated subject. The problem of how much to generalize is, of course, a thorny one for any scholar, and probably no two could ever agree on the exact balance to strike.

The organic structure of the volume is sound, and the complex narrative moves along smoothly. There is a great deal of attention given to detail and documentation which should be of value to future planners. The author has avoided the pitfall of partisanship, and in the mellowed perspective of time has treated colorful and controversial figures with impeccable restraint. This volume, along with other military medical volumes of the period, will form a basic reference library for the serious student or planner. —MAE M. LINK, Ph. D.

ESSENTIALS OF DERMATOLOGY, by *Norman Tobias*, M. D. 5th edition. 651 pages; 211 figures; 11 subjects in color. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$8.

This textbook for medical students and general practitioners has been widely used since the first edition appeared in 1941. It does not pretend to exhaustively discuss the etiologic, physiologic, pathologic, diagnostic, and therapeutic aspects of diseases of the skin. It is a brief, practical, and useful text for the student and practitioner.

The book is well illustrated with both black and white and colored plates, and the printing is excellent. Organization of the subject matter is practical and useful. Particularly helpful to the nonspecialist is the section included in each chapter on those aspects of nursing that are particularly germane to the diseases considered.

The chapter on general therapeutic suggestions will prove to be a most helpful guide to the beginner.

Dr. Tobias again has succeeded in presenting a wide and difficult subject in a concise and readable form, yet complete enough for everyday use. This book is highly recommended for students of medicine and the nonspecialist — *VICTOR R. HIRSCHMANN, Col., MC, USA*

SYMPOSIUM ON MYASTHENIA GRAVIS. Papers read at the First International Conference on Myasthenia Gravis, at Philadelphia, Pa., on December 8-9, 1954, under auspices of The Myasthenia Gravis Foundation, Inc., New York. *Henry R. Viets*, M. D., and *George D. Gammon*, M. D., Guest Editors. 742 pages; illustrated. Distributed by The Myasthenia Gravis Foundation, Inc., New York, N. Y., 1955.

This symposium includes 18 manuscripts read at the First International Conference on Myasthenia Gravis at Philadelphia, 8-9 December 1954, under the auspices of the Myasthenia Gravis Foundation.

All the papers are rather brief and to the point. There is a statement of the clinical problem, followed by discussions of the pharmacologic aspects of neuromuscular transmission, pathophysiology of the disorder, the relation of the thymus to the disease, drug therapy and special features of management including thymectomy, myasthenic and cholinergic crises, and pregnancy in myasthenia gravis. The quality of this group of papers reminds one of the excellent series published on neuromuscular disorders by this same journal in 1953.

This symposium is recommended and should be useful to physicians who have the responsibility for the management of patients with myasthenia gravis. — *JOHN W. KEMBLE, Col., MC, USA*

SYNOPSIS OF GYNECOLOGY, Based on the Textbook *Diseases of Women*, by *Robert James Crossen*, M. D., F. A. C. S. 4th edition. 255 pages; 132 illustrations, including frontispiece in color. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$5.25.

The author states in his preface that the synopsis is intended primarily as a less expensive volume for the student who does not wish

to purchase a larger, more detailed, and expensive textbook. It is also his intent to provide the general practitioner with a small and ready reference guide for the recall of basic principles in diagnosis and treatment of gynecologic disorders as encountered in daily practice.

These intentions have been successfully accomplished, and this book aptly fills an additional need which has been encountered by this reviewer; namely, for a very complete and general review of gynecology as would be desired by the general surgeon, particularly in the armed services, who may encounter few gynecologic conditions in his daily work. To the end that it supplies factual and handy statistical data and many excellent outlines and illustrations, it will serve the young teaching associate in gynecology as an excellent, quick pocket reference. The coverage of the field is most thorough while controversial points and full details are left to the larger text.

—JOHN A. PEASE, *Comdr., MC, USN*

BRAIN MECHANISMS AND CONSCIOUSNESS, A Symposium organized by The Council for International Organizations of Medical Sciences. Established under the joint auspices of UNESCO and WHO. Consulting Editors: *Edgar D. Adrian, Frederic Bremer, and Herbert H. Jasper.* Editor for the Council: *J. F. Delafresnaye, C. I. O. M. S., Paris, France.* 556 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1954. Price \$8.50.

This symposium presents the combined efforts of outstanding research workers from the fields of neuroanatomy, neurophysiology, neurosurgery, psychiatry, and psychology to clarify the scientific knowledge surrounding the neurologic basis of conscious mental processes and behavior. The study utilizes a wealth of new data obtained by serious, painstaking research. Recognizing that communications between various scientific disciplines always present difficulties and that the problem of consciousness in its complexity will not at present yield a simple, common-sense analysis, each discussant in this symposium drives incisively to his points of value. All of the work done emphasizes the increasing importance of a complicated, integrating system between the cortex and subcortical formations, generally described as the centrencephalic system and composed of many topographic subcortical nuclei, association tracks, and diffuse arrangements of neurons.

Every physician and every research worker truly interested in the scientific understanding of the motivation of human behavior and the genesis of consciousness can gain greatly from a study of the various presentations. Particularly interesting to psychiatrists and psychologists will be articles on the psychologic, psychiatric, and psychoanalytic aspects of the problem of consciousness by such outstanding research scientists as L. S. Kubie, D. McK. Rioch, H. H. Jasper, A. E. Fessard, K. S. Lashley, and others. Detailed neuroanatomic, neurophysiologic, and neuropathologic presentations by H. W. Magoun, G. Moruzzi, E. D. Adrian, W. Penfield, W. Grey Walter, and others will

greatly interest research workers concerned with resolving the location of consciousness.

Since "consciousness is a primary fact of existence" (D. O. Hebb) and one can only know "the inner world of consciousness directly, the outer world only by inference from the inner data" (J. C. Eccles), it must be recognized that an understanding of consciousness requires both the observer and the observed. This symposium provides a ring-side seat from which either the observed or the observer can truly delve into the mystery of consciousness. This publication should be readily available as a reference book wherever serious study of brain mechanisms and consciousness is carried on.

—LUCIO E. GATTO, Col., USAF (MC)

ARTHROPLASTY, by *St. J. D. Buxton*, M. B., B. S. 126 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$6.

This monograph is an attempt to cover the subject of arthroplasty of the various joints, including significant historical data and a review of recent contributions by other surgeons, and concluding with a cautious chapter of predictions on what the future holds. The bibliography is complete and includes most of the important literature on the subject.

Various joints are dealt with, but by far the greatest portion of the discussion is given to hip joint arthroplasty with the author submitting an evaluation of his own as well as other surgeons' results. His enthusiasm for the stem prosthesis with an acrylic head is not shared by a large number of orthopedic surgeons in the United States.

The chapters on the principles of postoperative treatment and rehabilitation are reasonably complete. The instructions are rather general and will be most helpful to those who are already acquainted with the trials encountered in the postoperative management of the reconstructed joint.

This monograph is recommended reading for orthopedists especially interested in the history of arthroplasty. The remainder makes interesting reading but falls somewhat short of being a classic reference work in the field.—CLIFFORD A. STEVENSON, Capt., MC, USN

JOINT LIGAMENT RELAXATION TREATED BY FIBRO-OSSEOUS PROLIFERATION, by *George Stuart Hackett*, M. D. With special reference to low back disability, trigger point pain and referred pain. 97 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$4.75.

The author has presented in monograph form his views on the anatomy, etiology, pathology, diagnosis, and treatment of painful joints. Based on 16 years of experience in therapy, including administration of over 3,000 injections, he has concluded that both local and referred pain in low back disability and in that of other joints is due to ligamentous instability. The methods of accurate diagnosis and localization of the trigger points are clearly described and stressed. Phe-

nomenal cures of all these conditions were obtained by the injection of these trigger points with a fibro-osseous proliferant, a wonderful procedure if it can be reduplicated by other physicians treating the same type of conditions.

The author has very adequately expressed his views and presented convincing evidence to support the soundness of his treatment but at times is repetitious. The book is satisfactorily illustrated with 17 black-and-white and line drawings.

The author has assumed that all physicians ignore the anatomy, function, and treatment of injuries to the ligamentous structure of joints. Although this may be an extreme view, too often the adequate treatment for ligamentous injuries is neglected. This results in complications which are considered and treated as separate entities without due regard to their primary cause.

This book should be read by every physician and be available for ready reference to every physician who treats the residuals of joint trauma.—JOSEPH W. BATCH, Col., MC, USA

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. *Preventive Medicine in World War II. Volume III: Personal Health Measures and Immunization.* 394 pages; illustrated. Prepared in the Historical Unit, Army Medical Service, Editor-in-Chief, Colonel John Boyd Coates, Jr., MC. Editor for Preventive Medicine, Ebbe Curtis Hoff, Ph. D., M. D. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$3.25.

This third volume in the series on "Preventive Medicine in World War II" covers the general field of health measures and immunization. The subject is broken down into chapters dealing with manpower selection, personal hygiene, clothing, nutrition, malnutrition and deficiency diseases, preventive psychiatry, accidental trauma, and immunizations.

The authors have, in narrative fashion, detailed the experiences, mistakes, and repetitive efforts of the past in relation to these various aspects of personal health measures. Each chapter is a condensation of a mass of reference material boiled down sufficiently to prevent the reader from becoming mired in detail. For those who wish to study the subject of each chapter in more detail the source material is listed accurately at the foot of each page.

Here in one volume reposes a wealth of information on the trials, errors, and accomplishments of the past which, but for their compilation in this book, would be lost to those responsible for planning for the future. Whether read by military or civilians, all of the chapters are interesting, and some are fascinating, not only in content but in style.

The chapter on clothing is introduced by an explanation of the physics and physiology involved in the control of temperature and

humidity problems as related to the body. A thorough understanding of this chapter by all medical and line officers will eliminate in the future much of the effective time lost in past wars from such related injuries as trench foot.

If this volume had not been compiled, it is conceivable that many of the mistakes of the past war would be repeated for lack of a single source of material on these subjects. In most chapters the experiences and developments are discussed in general and also in relation to war theaters. This is of additional aid to those seeking guidance in developing a global preventive medicine program.

—LESTER P. VEIGEL, Col., USAF (MC)

THE YEAR BOOK OF DRUG THERAPY (1955-1956 Year Book Series), edited by Harry Beckman, M. D. 560 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1956. Price \$6.

This yearbook, published each January, is based on the material in journals received through the preceding August.

The book is divided into sections on antibiotics and sulfonamides, cardiovascular diseases, surgery, et cetera, and within each section articles concerning new drugs, new information about old drugs, or new therapeutic approaches to particular diseases are abstracted. Editorial footnotes call attention to particularly notable deficiencies of or value in the articles abstracted in an attempt to tie isolated findings together and to give a more complete therapeutic concept. Articles reinforcing or contradicting each other are frequently reviewed together editorially.

This format plus a good index make this book the best available reference or review. Its yearly publication ensures current information, and the large number of both domestic and foreign journals reviewed guarantees coverage of any particularly important innovations. The book should be in all medical libraries and is heartily recommended to all physicians, from internes to specialists.

—CHRISTIAN GRONDECK, Lt. Col., MC, USA

DISEASES OF THE LIVER, Edited by Leon Schiff, M. D., Ph. D., with the collaboration of 27 contributors. Foreword by Cecil J. Watson, M. D., Ph. D. 738 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$16.

Advances in our knowledge of the liver, its diseases and their treatment, have been sufficient to warrant compilation in this sizable volume. The most important recent developments are said to be in the following fields: (1) knowledge of basic structure and function of the liver, (2) experimental production of liver disease, (3) viral hepatitis, (4) hepatic coma and nitrogen metabolism, (5) pathogenesis and treatment of cirrhosis, (6) treatment of hemochromatosis by phlebotomy, (7) copper metabolism in Wilson's disease, (8) needle biopsy of the liver, and (9) surgery for portal hypertension. Twenty-eight eminent workers have written on those aspects of liver disease in which they are well-

known experts. No single author could authoritatively cover all of this material before it became history. Dr. Schiff has so skillfully edited this book that it presents a balanced and thorough treatment of the subject, covering all important features without the omission of significant areas.

The gross and microscopic anatomy, physiology, and biochemistry of the liver are considered in 92 pages, followed by a chapter on experimental hepatic injury and three chapters on diagnosis and diagnostic tests and methods. The remaining 500 pages are devoted to disease entities and syndromes.

The focus of the book is predominantly clinical, and with few exceptions the contributors are persons whose daily activities devolve around the diagnosis and treatment of patients with liver disease. This book will be an extremely useful tool for anyone concerned with patients who have hepatic disease.

—BENJAMIN H. SULLIVAN, Jr., Col., MC, USA

A MANUAL OF FRACTURES AND DISLOCATIONS, by *Barbara Bartlett Stimson*, M. D., Med. Sc. D. 3d edition. 224 pages; 97 illustrations. Lea & Febiger, Philadelphia, Pa., 1956. Price \$4.50.

This book is a brief introduction to the subject of fractures and dislocations. It is written in an informal style with proper emphasis on conservative treatment of fractures, and occasionally indications are given for more radical intervention. The book is divided into a section on general treatment principles, followed by sections related to anatomic distribution of injury. Line drawings which are concise and clear are used as illustrative material, but methods mentioned in the text are not in all instances illustrated. This is especially true of the management of fractures by traction, and this discrepancy would lead to error unless other texts were used. Each fracture is briefly discussed as to diagnosis, etiology, incidence, treatment, and prognosis. It must be said, however, that in most instances the prognoses in patients with fractures are somewhat optimistic, and periods of immobilization for joint dislocations are unusually short. It is stated that a dislocated shoulder, for instance, need only be immobilized by a sling and swathe for a few days. This small text could serve well as an introduction to the treatment of fractures and dislocations for medical students and could be used as a guide for instruction. However, confronted with the problem of management of any specific fracture, one could hardly find enough material in this book and would be forced to seek other sources for guidance in definitive management.

—STERLING J. RITCHEY, Col., MC, USA

DISEASES OF THE LIVER AND BILIARY SYSTEM, by *Shelia Sherlock*, M. D. (Edin.). 720 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$10.

In this clear and practical guide to hepatic and biliary disorders, the author, an experienced authority, has used the functional approach. Throughout, the emphasis is on the disturbance of liver (and biliary)

function, yet the laboratory is kept in proper balance with bedside observation.

There are numerous excellent illustrations, and the large type and attractive use of bold and italic faces make this book exceptionally easy to read.

A special word of thanks should be offered Dr. Sherlock because she has managed to describe a subject of great complexity with admirable simplicity. In fact, American authors could learn a great deal from a study of this model of English medical literature.

Because of the interrelations between the liver and all metabolic disturbances and because of the many types of primary and secondary hepatic disturbances the discussions are, in many instances, relatively brief. Nevertheless practically all the essential information is presented. Therefore, this book will certainly appeal to the student, house officer, and practitioner. The research investigator would use the book for a handy reference, although he may have to refer to experimental papers for certain details. The text can be strongly recommended to all readers.—S. O. WAIFE, Lt. Comdr., MC, USNR

AN ATLAS OF OTOLARYNGIC PATHOLOGY. By Colonel J. E. Ash, USA (Ret.), M. D., and Muriel Raum, M. D., Published under the joint sponsorship of the American Academy of Ophthalmology and Otolaryngology, The American Registry of Pathology, and The Armed Forces Institute of Pathology. 572 pages; 2,024 figures on 420 plates. American Registry of Pathology, Washington, D. C., 1956. Price \$20.

This is an extensive volume that covers a variety of lesions found in the general field of pathology in addition to diseases of the respiratory tract, neck, and ear. The format of the book is excellent, and for the most part the many black and white photomicrographs are clear and readily understandable.

The first part is devoted to a section on general pathology and presents a variety of subjects such as inflammation, pigmentation and degeneration, deficiency diseases, miscellaneous diseases of bone, and dermatoses. This section, I believe, could be deleted as it is adequately covered in the texts of general pathology readily available. However, on the whole the field of otolaryngic pathology is more extensively covered than could be found anywhere else. The plates on diseases and tumors of the ear are particularly good and well documented. This book will be a ready reference to the general pathologist as well as the otolaryngologist.—VERNON E. MARTENS, Capt., MC, USN

ROENTGEN INTERPRETATION OF FRACTURES AND DISLOCATIONS, by Joseph Levitin, M. D., and Ben Colloff, M. D. 265 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$8.50.

In this first edition, a roentgenologist and an orthopedic surgeon have collaborated to produce a precise and practical guide to the reduction and immobilization of fractures. The title of the book is somewhat misleading. As stated in the foreword, the main purpose of the book is to

describe what constitutes generally accepted satisfactory reduction with emphasis on the important alinements to be restored or preserved as an aid to the roentgenologist.

The book serves as a handy reference of the essential normal x-ray anatomy of the more common sites of fracture and dislocation, the deformities usually produced by fracture or dislocation, the accepted position of reduction, and the usual time of immobilization. Methods of reduction, means of immobilization, and x-ray evidence of healing progress or complications are not included, except for several reproductions of roentgenograms demonstrating normal and abnormal healing progress in fractures of the femoral neck.

Aside from the 16 reproductions of hip roentgenograms, the parts are represented by diagrams which include only the essential anatomy and which are adequately labeled. Several errors in labeling are noted. Approximately 50 per cent of the text is devoted to the diagrams. Fractures of the skull and facial bones are not included. Fractures and dislocations of the spine are treated rather sketchily in a total of 18 pages as compared to 10 pages devoted to traumatic dislocation of the hip. Included as Appendix A are two pages of "bone age charts." Appendix B consists of five pages of line drawings of common appliances used in internal fracture fixation.

Although this volume is not intended as a complete reference book, it adequately serves the limited purpose intended by the authors.

—DELL F. DULLUM, Col., MC, USA

CLINICAL ELECTROCARDIOGRAPHY, Part 1, The Arrhythmias, With an Atlas of Electrocardiograms, by Louis N. Katz, M. D., and Alfred Pick, M. D. 737 pages; 415 illustrations. Lea & Febiger, Philadelphia, Pa., 1956. Price \$17.50.

This text on arrhythmias constitutes Part 1 and presumably Volume 1 of others to follow on the subject of clinical electrocardiography by the authors. Much of the basic material is an expansion of that contained in the chapter on arrhythmias as published in the second edition of *Electrocardiography*, a text prepared by the senior author in 1946. The original material has been expanded to include advances and some of the newer concepts. Old illustrations and legends have been revised and many new ones have been added. New chapters dealing with dynamics of cardiac arrhythmias, principles of therapy, general aspect of block, and arrhythmias in the pre-excitation syndrome and those in the dying patient also have been added. Two useful appendices are added, the first concerning technic in the diagnosis of arrhythmias, the second containing a detailed coding system.

The contents are divided into two sections. Section 1, consisting of six short chapters, discusses the general aspects essential to prepare the reader for the detailed considerations of the individual disturbances of rhythm, which constitute Section 2. A bibliography is given at the end of Section 1 and at the end of each of the 10 chapters

constituting Section 2. The general plan of this book has been to separate the text from the illustrative electrocardiograms, the latter being placed at the end of each chapter. Each illustrative tracing has an extensive explanatory legend and can be used without reference to the text. The reader will find an analogue of most, if not all, of the records he is likely to encounter. Inasmuch as 497 pages are used solely for figures and legends, this publication is more of an atlas than a textbook.

There are disappointments in this new volume. In the theoretic discussions, the authors do not give due consideration to the unitary theory of origin of atrial arrhythmias. They ignore the existence of acceleration of conduction through the A-V nodal tissues, in spite of the fact that pages are given to discussion of delayed conduction through these same tissues. No reference is given in the extensive bibliographies to the recent work of Prinzmetal on these subjects. The authors apologize to some extent for this omission in the preface by stating: "We are well aware that some of the views expressed in this volume are not entirely in agreement with the concepts that are held by other serious workers in the field of arrhythmias." This, however, will not help the uninformed reader who will be unable to reconcile the terminology and ideas he reads in current literature with this "current text." Likewise, it is unfortunate that the terminology "auricular flutter and fibrillation" was used instead of the more correct and acceptable term of "atrial flutter and fibrillation."

—THOMAS W. MATTINGLY, Col., MC, USA

OPERATIVE TECHNIC IN SPECIALTY SURGERY, edited by Warren H. Cole, M. D., F. A. C. S., with 67 contributing authors. A Companion Volume to *Operative Technic in General Surgery*, published Oct. 1955. 2d edition. 967 pages; illustrated. Appleton-Century-Crofts, Inc., New York, N. Y., 1956. Price \$20. (\$37.50 for the 2-volume set).

This is the second edition of this fine work which covers the specialty fields of cardiovascular and thoracic surgery, plastic and reconstructive surgery, operative orthopedic surgery, neurosurgery, gynecologic surgery, and surgery of the male genito-urinary system. The greatest changes occur in the new edition in the fields of cardiovascular and thoracic surgery, and the chapter on plastic and reconstructive surgery has been greatly changed and improved.

In view of the present complexity in the fields of specialty surgery, the important function of a book of this type is to provide the general surgeon with a bird's-eye view of present operative methods, admitting that the minutiae and patient care cannot possibly be consolidated in one volume. The book has accomplished this objective in a superb manner. As such, it becomes a useful handbook for a general review of specialty surgery, and for beginning a more detailed study using the fine bibliography appended to each chapter.

The sections on thoracic surgical subjects include complete descriptions of modern operations on the heart, aorta, and lungs. Details

are given of such current technics as aortic resection, cardiac resuscitation, extracorporeal circulation, and repair of cardiac septal defects. Possibly the bird's-eye view of this important field could be improved by a modicum of editing. For example, the excellent sections on vascular injuries and pleuropulmonary operations could stand expansion at the expense of such items as the discussion of endo-aneurysmorrhaphy, of historic interest only, and the statistical polemic on results after operation for coronary artery disease. To me, the latter sections seem out of place in this kind of book.

The section on plastic and reconstructive surgery has been greatly enlarged and improved over the previous edition, and also includes a detailed description of general surgery of the neck.

This is an excellent edition, and of great value to the general surgeon. The quality of printing, binding, and halftone reproduction is excellent. It would be interesting to know whether the replacement of many of the halftone illustrations by suitable line drawings would reduce the price of this important volume to make it more readily available to the young surgeon in training.—LEWIS L. HAYNES, *Capt., MC, USN*

Clinical Recognition and Management of DISTURBANCES OF BODY FLUIDS, by *John H. Bland*, M. D. 2d edition. 522 pages; illustrated. W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$11.50.

This is a genuinely useful book. In it Dr. Bland has logically assembled the great body of information now available on the behavior of water and electrolytes in health and disease. With this information he has attempted to formulate a "practical pathophysiologic interpretation of metabolic deviations of water, electrolyte, and hydrogen ion metabolism in all disease states for clinical utilization at the bedside." He has succeeded to a remarkable degree. Basic considerations are discussed in five chapters. Other entire chapters are devoted to separate discussions of fluid and electrolyte problems in relation to circulatory failure, liver disease, pediatrics, pulmonary disease, geriatrics, surgery, renal disease, effects of heat, diabetes mellitus, adrenal insufficiency, corticotropin and corticoids, central nervous system injury and disease, and problems related to physical stress such as roentgen irradiation.

Nomenclature and concepts have been simplified as much as possible without sacrifice of scientific accuracy. Even so, a considerable fund of specialized knowledge is necessary for intelligent reading. Dr. Bland makes a strong plea for increased use of bedside observation and clinical judgment in treating the type of problems dealt with here. In doing this, he makes statements which may appear to question the practical value of adjunctive laboratory means such as the flame photometer. This is regrettable but undoubtedly unintentional. Since these things are becoming increasingly available, even under relatively modest circumstances, it would be unfortunate if any clinician were discouraged from becoming sufficiently acquainted with them.

The author's style is clear and interesting, and he makes good use of the teaching device of repetition. Documentation is good and excellent tables, charts, and illustrations have been liberally provided. Many "cartoon" type illustrations are provided as a supplement to the text and the conventional diagrams. Indexing is adequate but could be improved by indexing authors separately. This book is highly recommended reading for all physicians and medical students.

—JOHN K. SPITZNAGEL, Lt. Col., MC, USA

SUBPHRENIC ABSCESS, by H. R. S. Harley, M. S., F. R. C. S. A Monograph in The Bannerstone Division of American Lectures in Surgery, edited by Michael E. DeBakey, M. D., and R. Glen Spurling, M. D. Thoracic Surgery Division, edited by Brian Blades, M. D. 216 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$7.

This monograph is based on a study of the records of 183 patients suffering from subphrenic abscess and on a study of the literature. The subject matter concerns the author's concept of the anatomy of the subphrenic region. The pathway of infection to this region is explained and the way infection may spread across the diaphragm in either direction is discussed. The value of radiologic examination and the changes produced by an abscess under the diaphragm are described.

The symptoms, signs, and clinical varieties of subphrenic abscess and the other complications so commonly found in these patients are given lengthy consideration. Also the influence of complications on the clinical picture and on the mortality is stressed. The condition of subphrenitis without abscess formation, which gives rise to all the constitutional and local changes produced by a subphrenic abscess except those of a space-occupying lesion or of a gas-containing cavity, is described. Constitutional and local signs of infection may subside due to treatment with chemotherapeutic agents and do not recur. If resolution of the constitutional and local features of infection does not take place or if, after treatment is stopped, they recur, the presence of an abscess must be assumed, provided other complications are not present, and drainage should be instituted without delay.

Special reference to the importance of chemotherapy and to the route of drainage of subphrenic abscess is made. A plea for the universal adoption of extraserous approaches to the subphrenic spaces is made by showing the difference in mortality between the trans-serous and extraserous drainage.

The author has shown that, with early diagnosis, localization, and correct treatment, the mortality of subphrenic abscess should not exceed 10 per cent. This book summarizes the subject of, and the literature on, subphrenic abscess and is a ready reference for the treatment of the occasional case occurring in the experience of each physician and surgeon. The illustrations are good, and the book is adequately indexed and contains an excellent bibliography.

—HERBERT T. BERWALD, Col., MC, USA

COLLECTED PAPERS ON AVIATION MEDICINE. AGARDograph No. 6. Presented at Aeromedical Panel Meetings of the Advisory Group for Aeronautical Research and Development, Palais de Chaillot, Paris. Published for and on behalf of Advisory Group for Aeronautical Research and Development, North Atlantic Treaty Organization. 218 pages. Interscience Publishers, Inc., New York, N. Y., 1955. Price \$5.

This book is a compendium of 18 technical papers presented at several meetings of the Advisory Group for Aeromedical Research and Development (AGARD). The topics range all the way from Arctic survival problems to night vision. Eleven of the papers are reprinted from the Fourth Meeting of the Aeromedical Panel, which met in London in September 1953. Four of the papers are in French; the rest are in English.

It is difficult to consider the collection of papers as a book, as they have little in common. A more rational approach is to consider each paper on its own.

There is a very complete paper entitled "Tolerance to Abrupt Deceleration" by John Paul Stapp, including his protocols and several hitherto unpublished photographs. This makes this book a must for those interested in the subject of deceleration. The book is dominated by the 50 pages of text and 23 pages of illustrations devoted to this article.

Three of the authors are from the Royal Air Force Institute of Aviation Medicine at Farnborough. Ruffel Smith discusses aircraft cockpits from the anthropometric standpoint. There is a short article on the physiologic requirement of pressure cabins by Roxburgh, and an interesting article on rapid decompression by Fryer.

A paper entitled "Recent Advances of Instrumentation of Interest in Aviation Medicine" puts in one place the information on pressure transducers, spectrometric methods of gas analysis by quantitative emission spectroscopy, and the Rahn-Oris technic and other methods of intermittent and continuous sampling of expired air. Such diverse topics are considered from the standpoint of instrumentation rather than the resultant findings; it is a refreshing approach and one of interest to the student in the field. The article is well annotated with references and covers some 30 pages.

There is an interesting discussion by Van Wulfften Palthe on a test for detecting epilepsy—a simple paper and pencil test. In fact, he hints that the test may induce an attack in a latent epileptic.

There are general papers by such well-known men in aviation medicine as Benson, Grandpierre, Lo Monaco, and Bergeret; these emphasize the international nature of AGARD meetings.

The information contained in some of the papers has been published elsewhere. Nevertheless the book is worth buying. The paper by Stapp gives the book particular value to individuals and institutions who are interested in collecting literature in aviation medicine.

—VINCENT M. DOWNEY, Col., USAF (MC)

A TEXTBOOK OF ENDODONTOLOGY, by *Edgar D. Coolidge, M. S., D. D. S., LL. D. (Hon. Loyola)*, and *Robert G. Kesel, D. D. S., M. S.* 2d edition, 366 pages; 345 illustrations on 210 figures and 1 plate in color. Lea & Febiger, Philadelphia, Pa., 1956. Price \$7.50.

As stated in the preface, this volume was written because of "the desire of the author to present a text that will be helpful to both student and practitioner," and it offers the undergraduate dental student and general practitioner a clear, descriptive, and authoritative presentation of an important branch of health service.

The chapters devoted to therapeutics, dental caries, and the etiology of dental pain are lucid and well organized with excellent accompanying tables and illustrations. Of particular interest, especially to the military dental officer, is the chapter on dental pain experienced under conditions of low barometric pressure and during high-altitude flights, both actual and simulated.

The chapters devoted to vital and nonvital pulps, partial and complete pulp removal, and the filling of root canals are written in detail, with descriptive illustrations and tables. In conjunction with the clinical procedures, there is a thorough coverage of the latest technics and drugs in antibiotic therapy. This is followed by an excellent discussion of the biologic and clinical support of the theory of focal infection and pulpless teeth.

The information in this volume is of great value in the treatment of pulp pathology and root canal therapy. The book is a necessary reference for the libraries of general practitioners and clinicians at military and dental facilities who wish to have available a concise treatise on the subject of endodontology, with a well-balanced treatment of sound, logical theory and exact clinical procedures.

—JOHN R. McEVROY, Lt. Col., USAF (DC)

COLOR ATLAS OF ORAL PATHOLOGY, Histology and Embryology, Developmental Disturbances, Diseases of the Teeth and Supporting Structures, Diseases of the Oral Mucosa and Jaws, Neoplasms. Prepared under the auspices of the U. S. Naval Dental School of the National Naval Medical Center, Bethesda, Md. 188 pages; 461 figures in color. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$12.

This concise book admirably fulfills its stated purpose to present, in pictures, basic knowledge which will lead to early diagnosis and treatment of diseases which occur in the oral cavity.

The chapters cover (1) a brief presentation of histology and embryology as they relate to selected normal tissues; (2) developmental disturbances; (3) diseases of teeth and supporting structures; (4) diseases of the oral mucosa and jaws; and (5) neoplasms. The bibliography cites numerous selected references for detailed study of the various oral diseases. There is an excellent topic index.

To accomplish his purposes, the author has used 461 superb illustrations, all of which are in color except for the roentgenograms. The

color plates include reproductions of transparencies, sketches, and lithographs. Such profuse visual information provides precisely the aid needed by the clinician or student for swift diagnosis and proper treatment planning of all the oral diseases.

This book emphasizes the visual portrayal of clinical, roentgenographic, and microscopic appearances of the various oral diseases. Written material is brief and is confined to the page on which the entity is illustrated. The condensed information includes a concise definition of the condition illustrated and a short discussion of the pertinent local and general aspects.

The author is to be complimented highly for producing a compact book which has both reader interest and scientific merit. This atlas provides quick and authoritative information in a practical handbook so valuable it deserves a place in every dental library.

—KENNETH R. ELWELL, Col., USAF (DC)

THE YEAR BOOK OF NEUROLOGY, PSYCHIATRY AND NEUROSURGERY (1955-1956 Year Book Series). Neurology, edited by Roland P. Mackay, M. D. Psychiatry, edited by S. Bernard Wortis, M. D. Neurosurgery, edited by Percival Bailey, M. D., and Oscar Sugar, M. D. 576 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1956. Price \$7.

This annual abstract of the current literature continues to be an important contribution as a time-saver to the student, the busy practitioner, and the specialist. It is gratifying that the recent literature reflects a more balanced and integrated approach to both neurophysiologic and psychic functioning.

In the field of neurology, the editor feels that the development of an effective vaccine against acute anterior poliomyelitis was the outstanding event of 1955. There has been continued intensive work on the functions of the temporal lobe and the role played by the "visceral brain" in the behavior of the organism. That the temporal lobes are not the "seat of emotion" is apparent from investigations on the cingulate gyrus, the thalamus, the hypothalamus, and other areas. Encouraging progress is evident in the field of degenerative diseases, some of which, like progressive lenticular degeneration, may prove to be of metabolic origin and perhaps eventually amenable to therapy. Studies of the convulsive disorders reveal that electroencephalographic patterns are not readily translatable into clinical terms.

In the section on psychiatry, the year will be remembered as one of experimentation and clinical use of several new drugs. However, a difficult problem is a need for clearer criteria in the choice of drugs. One can predict with some assurance that newer and better anxiety- and tension-relieving drugs will soon become available and that fewer lobotomies will be done. Newer electric and ultrasonic devices will be more effective in the treatment of the mentally ill patient. However, much handicap is imposed on psychiatry and mental health programs by the deplorable lack of personnel and facilities. Hospital architecture

A TEXTBOOK OF ENDODONTOLOGY, by Edgar D. Coolidge, M. S., D. D. S., LL. D. (Hon. Loyola), and Robert G. Kesel, D. D. S., M. S. 2d edition. 366 pages; 345 illustrations on 210 figures and 1 plate in color. Lea & Febiger, Philadelphia, Pa., 1956. Price \$7.50.

As stated in the preface, this volume was written because of "the desire of the author to present a text that will be helpful to both student and practitioner," and it offers the undergraduate dental student and general practitioner a clear, descriptive, and authoritative presentation of an important branch of health service.

The chapters devoted to therapeutics, dental caries, and the etiology of dental pain are lucid and well organized with excellent accompanying tables and illustrations. Of particular interest, especially to the military dental officer, is the chapter on dental pain experienced under conditions of low barometric pressure and during high-altitude flights, both actual and simulated.

The chapters devoted to vital and nonvital pulps, partial and complete pulp removal, and the filling of root canals are written in detail, with descriptive illustrations and tables. In conjunction with the clinical procedures, there is a thorough coverage of the latest technics and drugs in antibiotic therapy. This is followed by an excellent discussion of the biologic and clinical support of the theory of focal infection and pulpless teeth.

The information in this volume is of great value in the treatment of pulp pathology and root canal therapy. The book is a necessary reference for the libraries of general practitioners and clinicians at military and dental facilities who wish to have available a concise treatise on the subject of endodontology, with a well-balanced treatment of sound, logical theory and exact clinical procedures.

—JOHN R. McEVoy, Lt. Col., USAF (DC)

COLOR ATLAS OF ORAL PATHOLOGY, Histology and Embryology, Developmental Disturbances, Diseases of the Teeth and Supporting Structures, Diseases of the Oral Mucosa and Jaws, Neoplasms. Prepared under the auspices of the U. S. Naval Dental School of the National Naval Medical Center, Bethesda, Md. 188 pages; 461 figures in color. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$12.

This concise book admirably fulfills its stated purpose to present, in pictures, basic knowledge which will lead to early diagnosis and treatment of diseases which occur in the oral cavity.

The chapters cover (1) a brief presentation of histology and embryology as they relate to selected normal tissues; (2) developmental disturbances; (3) diseases of teeth and supporting structures; (4) diseases of the oral mucosa and jaws; and (5) neoplasms. The bibliography cites numerous selected references for detailed study of the various oral diseases. There is an excellent topic index.

To accomplish his purposes, the author has used 461 superb illustrations, all of which are in color except for the roentgenograms. The

color plates include reproductions of transparencies, sketches, and lithographs. Such profuse visual information provides precisely the aid needed by the clinician or student for swift diagnosis and proper treatment planning of all the oral diseases.

This book emphasizes the visual portrayal of clinical, roentgenographic, and microscopic appearances of the various oral diseases. Written material is brief and is confined to the page on which the entity is illustrated. The condensed information includes a concise definition of the condition illustrated and a short discussion of the pertinent local and general aspects.

The author is to be complimented highly for producing a compact book which has both reader interest and scientific merit. This atlas provides quick and authoritative information in a practical handbook so valuable it deserves a place in every dental library.

—KENNETH R. ELWELL, Col., USAF (DC)

THE YEAR BOOK OF NEUROLOGY, PSYCHIATRY AND NEUROSURGERY (1955-1956 Year Book Series). Neurology, edited by Roland P. Mackay, M. D. Psychiatry, edited by S. Bernard Wortis, M. D. Neurosurgery, edited by Percival Bailey, M. D., and Oscar Sugar, M. D. 576 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1956. Price \$7.

This annual abstract of the current literature continues to be an important contribution as a time-saver to the student, the busy practitioner, and the specialist. It is gratifying that the recent literature reflects a more balanced and integrated approach to both neurophysiologic and psychic functioning.

In the field of neurology, the editor feels that the development of an effective vaccine against acute anterior poliomyelitis was the outstanding event of 1955. There has been continued intensive work on the functions of the temporal lobe and the role played by the "visceral brain" in the behavior of the organism. That the temporal lobes are not the "seat of emotion" is apparent from investigations on the cingulate gyrus, the thalamus, the hypothalamus, and other areas. Encouraging progress is evident in the field of degenerative diseases, some of which, like progressive lenticular degeneration, may prove to be of metabolic origin and perhaps eventually amenable to therapy. Studies of the convulsive disorders reveal that electroencephalographic patterns are not readily translatable into clinical terms.

In the section on psychiatry, the year will be remembered as one of experimentation and clinical use of several new drugs. However, a difficult problem is a need for clearer criteria in the choice of drugs. One can predict with some assurance that newer and better anxiety- and tension-relieving drugs will soon become available and that fewer lobotomies will be done. Newer electric and ultrasonic devices will be more effective in the treatment of the mentally ill patient. However, much handicap is imposed on psychiatry and mental health programs by the deplorable lack of personnel and facilities. Hospital architecture.

and our clinical practices will soon be modified by new and important advances.

In the neurosurgical section, it is noteworthy that indiscriminate "psychosurgery" is justly deprecated. There is considerable improvement in the technic of angiography and ventriculography with the real possibility of lessening the morbidity in these procedures. Stereotaxic investigations continue, and there now exists the possibility of destruction of the hypophysis. There is no effective pituitary hormone for replacement of an absent hypophysis, although a combination of cortisone, testosterone, and thyroid extract seems to act fairly well.

The yearbook continues to fulfill its mission, and the usual high standards of reporting have been maintained in the current volume.

—RICHARD R. CAMERON, Col., MC, USA

BING'S LOCAL DIAGNOSIS IN NEUROLOGICAL DISEASES, by Webb Haymaker, M. D. With Chapters by Richard G. Berry, M. D., Bernard S. Epstein, M. D., and Paul I. Yakovlev, M. D. Translated, Revised, and Enlarged from the Fourteenth German Edition. 478 pages; 225 illustrations, including 9 in color. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$16.75.

This volume is a completely revised and enlarged edition of a venerable neurologic classic; the present edition is virtually a new book due to an exhaustive revision in the light of the latest information.

The popularity of the method of presentation of this 478-page work is illustrated by the fact that Bing's first volume on local neurologic diagnosis was published in 1911 and has survived many editions, both in English and the original German.

The present edition covers in detailed fashion the localization of lesions of all parts of the central nervous system. A very large bibliography is included, and there are 225 well-selected photographs and diagrams. Brief sections on roentgenography and electrical methods of diagnosis are presented, apparently only to indicate the value of these methods, since this material is very sketchy and incomplete.

The sections on localization of lesions of the brain stem and cranial nerves and the detailed consideration of the many arterial occlusive syndromes are considered especially praiseworthy. The information is presented in rather dogmatic fashion, and there are those who will disagree with some of the conclusions reached. However, such material can hardly be useful if presented in an argumentative fashion, and the opinions are based upon the most generally accepted knowledge.

The main value of this book is to serve as a reference for making anatomic diagnoses in neurologic cases, and to give meaning to the many neurologic signs and symptoms encountered in clinical work. The practicing neurologist or neurosurgeon will probably keep it on his desk. It will also be extremely useful for any neurologically minded medical scholar who wishes to locate central nervous system lesions.

New Books Received

Books received by the *U. S. Armed Forces Medical Journal* are acknowledged in this department. Those of greatest interest will be selected for review in a later issue.

- TEXTBOOK OF BIOPHYSICAL CHEMISTRY, by *Eduard Staunton West*, Ph. D. 2d edition. 399 pages; illustrated. The Macmillan Co., New York, N. Y., 1956.
- AN ATLAS OF ANATOMY, by *J. C. Bosleau Grant*, M. C., M. B., Ch. B., F. R. C. S. (Edin.). 4th edition. 8½ by 11 inches in size. 556 pages; 714 figures, in color, arranged in the regional manner. The Williams & Wilkins Co., Baltimore, Md., 1956. Price \$15.
- REHABILITATION TRENDS—MID CENTURY TO 1956. 96 pages; illustrated. *Institute for the Crippled and Disabled*, New York 10, N. Y., 1956. Price, 1-10 copies, \$2.00 each; 11 or more copies, \$1.85 each, plus a mailing and handling charge of 20 cents per copy, within the continental limits of the U. S. A.
- Williams OBSTETRICS, by *Nicholson J. Eastman*. 11th edition. 1,212 pages; illustrated. Appleton-Century-Crofts, Inc., New York, N. Y., 1956.
- NERVE IMPULSE, Transactions of the Fifth Conference, September 20, 21, and 22, 1954, Princeton, N. J., edited by *David Nachmansohn*, M. D., and *H. Houston Merritt*, M. D. 256 pages; illustrated. Josiah Macy, Jr. Foundation, New York, 1956. Price \$4.50.
- PSYCHOLOGY, PSYCHIATRY and the PUBLIC INTEREST, edited by *Maurice H. Krout*, Ph. D. 217 pages. University of Minnesota Press, Minneapolis, Minn., 1956. Price \$4.
- ATHLETIC INJURIES, Prevention, Diagnosis and Treatment, by *Augustus Thordike*, M. D. 4th edition. 252 pages; 113 illustrations. Lea & Febiger, Philadelphia, Pa., 1956. Price \$4.50.
- A Manual of the COMMON CONTAGIOUS DISEASES, by *Philip Moen Stirson*, M. D., and *Horace Louis Hodes*, M. D. 5th edition. 624 pages; 84 illustrations and 10 plates, 8 in color; 16 tables. Lea & Febiger, Philadelphia, Pa., 1956. Price \$8.50.
- ENVIRONMENT AND THE DEAF CHILD, by *Steven Getz*, Ph. D. 173 pages. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$3.75.
- GROUP PROCESSES, Transactions of the Second Conference, October 9, 10, 11, and 12, 1955, Princeton, N. J., edited by *Bertram Schaffner*, M. D. 255 pages; illustrated. Josiah Macy, Jr. Foundation, New York, N. Y., 1956. Price \$3.50.
- BASIC READINGS ON THE MMPI IN PSYCHOLOGY AND MEDICINE, edited by *George Schlager Welsh* and *W. Grant Dahlstrom*. 656 pages. University of Minnesota Press, Minneapolis, Minn., 1956. Price \$8.75.
- FUNDAMENTALS OF CHEMISTRY AND APPLICATIONS, by *Charlotte A. Francis*, A. M., and *Edna C. Morse*, R. N., A. M., Ed. D. 4th edition. 543 pages; illustrated. The Macmillan Co., New York, N. Y., 1956.

PSYCHIATRIC RESEARCH REPORTS 5, of the American Psychiatric Association. "Research Techniques in Schizophrenia." Edited by Members of the Committee on Research, 1955-1956. Jacques S. Gottlieb, M. D., Chairman. Papers presented at the APA Mid-Atlantic Regional Research Conference, Georgetown University School of Medicine, Department of Psychiatry, Washington, D. C., March 9-10, 1956. 153 pages; illustrated. Published by American Psychiatric Association, Washington 6, D. C., June 1956. Price \$2.

THE PRACTICE OF MEDICINE, edited by Jonathan Campbell Meakins, C. B. E., M. D., LL. D., D. Sc. 6th edition. 1,916 pages; 318 illustrations, including 4 in color. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$16.

ACUTE RESPIRATORY ILLNESS CAUSED BY ADENOVIRUSES

A Military Problem

MAURICE R. HILLEMAN, *Ph. D.*

THE ACUTE respiratory illnesses of man present a major medical problem to the armed services in time of peace and more prominently in time of war. The magnitude of the problem in the U. S. Army during the last World War is illustrated in the example cited by Duff:

During the period of World War II, 1942-1945, from a mean strength of 6,076,135 there were 4,086,562 admissions for common respiratory disease recorded by the United States Army. The average time lost from duty by a person admitted for treatment of common respiratory disease during this period was 6.5 days The 4,086,562 cases admitted during the war period thus resulted in approximately 26.5 million man-days lost from duty, or approximately 18,000 each day of the war. An Army division is composed of 15,000 personnel. Thus, more than equivalent strength of one Army division were absent from duty every day of the war because of the common respiratory diseases.¹

During World War II, the members of the Commission on Acute Respiratory Diseases conducted extensive investigations of the respiratory illnesses of soldiers in an effort to delineate the clinical syndromes and to elucidate the causes wherever possible.

Certain portions of this paper were presented before the Military Preventive Medicine Section at the 105th Annual Meeting of the American Medical Association, Chicago, Ill., on 14 June 1956.

From Walter Reed Army Institute of Research, Washington, D. C.

These workers²⁻⁴ observed that, aside from respiratory illnesses caused by bacteria or known viruses or from the common cold, there remained a large bulk of acute respiratory illnesses of unknown causation. These belonged in the general category of "febrile catarrhs" differentiated from influenza by Stuart-Harris, Andrewes, and Smith⁵ in 1938. The members of the Commission recognized at least three distinct clinical entities among the cases of "febrile catarrh" which they referred to as undifferentiated acute respiratory disease (ARD), nonstreptococcal exudative pharyngitis, and primary atypical pneumonia (PAP). They demonstrated the separate causes of ARD, PAP (associated with the development of cold agglutinins), and the common cold based on the results of transmission experiments^{6,7} in human volunteers by employing filtered throat washings from patients. In further epidemiological studies, it was shown^{1,2,4,8} that epidemics of ARD occurred in recruits but not in "seasoned" men and that immunity seemed to follow this infection.

CAUSES

During and following World War II, numerous attempts were made to recover the virus of ARD in experimental laboratory hosts but none was successful. During 1953, human cell tissue culture was first applied to the problem, and this resulted in the independent discovery by Rowe and associates⁹ and by Hilleman and Werner¹⁰ of a new family of viruses which inhabit the respiratory tract of man. The viruses (adenoid degenerative or AD) of Rowe and co-workers⁹ were recovered as "masked" agents from surgically removed human adenoidal tissue being cultivated in tissue culture. The respiratory infection agents (RI) discovered by Hilleman and associates,^{10,11} which included types now designated 3, 4, and 7, were recovered from throat washings of military patients with ARD or PAP in an epidemic. The prototype strain RI-67, as well as other viruses recovered in the epidemic, were shown by serologic methods to be related causatively to the disease in the recruits. Following this, Dingle and associates^{12,13} showed by retrospective serodiagnosis that the RI-67 virus was related to cases of ARD which occurred among soldiers during World War II.

The new family of respiratory viruses has been designated by several names in the past. Huebner and associates¹⁴ and Rowe and co-workers¹⁵ have used the name adenoidal-pharyngeal-conjunctival (APC) viruses. Hilleman and associates^{10,11,16} referred to these agents as the RI family of viruses and Ginsberg and co-workers^{13,17} designated certain of the agents as ARD viruses. More recently a new name, Adenovirus,¹⁸ was adopted by the principals working in this field, and it was agreed that the previous designations of RI, APC, and ARD be no longer used.

Huebner and associates¹⁴ and others^{11, 13, 19-21} have shown that there are at least 14 distinct serotypes among the agents of the Adenovirus family. These serotypes are readily distinguished by the serum neutralization technic employing monotypic rabbit antisera. On the other hand, all the types of virus elaborate a common group-specific "soluble" complement-fixing antigen^{10, 14, 18, 22, 23} which can be separated readily from the virus by filtration or centrifugation procedures. Morphologically, the type 4 RI-87 and type 2 AD-6 strains have been shown to resemble influenza virus and to consist of spherical elementary bodies around 100 $m\mu$ in diameter.²³ The CF antigen is of smaller size.

CLINICAL FINDINGS

The clinical findings in patients with acute respiratory illness caused by the Adenoviruses indicate that all segments of the respiratory tract may be affected, the symptoms and signs in any particular patient depending upon the degree of damage and the location of the areas involved. In a recent study by Dascomb and Hilleman¹⁴ of 45 proved cases of acute respiratory illness caused by the Adenoviruses (predominantly or entirely type 7 virus) in newly recruited soldiers, it was observed that the most prominent clinical features were fever, pharyngitis, and severe cough. These were accompanied by constitutional symptoms such as headache, malaise, chills, myalgia, and dizziness which were usually mild. About half the patients developed discrete or confluent patches of nonbacterial white exudate on the hyperplastic lymphatic tissue in their throats, and the majority exhibited a coryzal feature. Laryngitis with hoarseness was a common complaint. Bilateral conjunctivitis and lymphadenopathy of the head and neck region were commonly observed among the patients studied. Lower respiratory tract involvement consisting of tracheobronchitis and bronchiolitis was a frequent finding, and about 16 per cent presented roentgenographic evidence of pneumonitis. The mean maximum temperature in the patients was about 103°F, and the fever lasted approximately 6 days on the average. The average hospital stay was around 10 days.

These disease conditions are commonly referred to as grippe, catarrhal fever, virus pneumonia, acute pharyngitis, or severe colds. More specifically, they belong in four respiratory disease entities established by the Commission on Acute Respiratory Diseases²⁻⁴ during World War II [*viz.*, undifferentiated acute respiratory disease (ARD), nonstreptococcal exudative pharyngitis, bronchitis resembling atypical pneumonia (Br-AP), and primary atypical pneumonia (PAP) (unassociated with the development of cold agglutinins)] and the syndrome of pharyngoconjunctival fever described more recently by Parrott and co-workers²⁴ and by Bell and others.²⁵ Collectively, these entities belong in the syndrome of febrile catarrh established in 1938 by Stuart-Harris, Andrewes,

and Smith to distinguish an illness having catarrhal aspects but otherwise resembling influenza. Kjellen¹⁶ in Sweden has shown that viruses of the Adenovirus family may be involved also in certain cases of mesenteric lymphadenitis, and Jawetz and associates²⁰ have presented evidence implicating the Adenoviruses in patients with keratoconjunctivitis. The Adenoviruses do not appear to be associated with the ordinary common cold in which there is a watery discharge with little or no fever,^{10,13,16,17} with primary atypical pneumonia in which the test for cold or Streptococcus MG agglutinin becomes positive,^{10,13,16,17,22,27} with psittacosis or ornithosis, with Q fever, or with influenza A, B, and C.

There is no specific therapeutic treatment for Adenovirus infections.¹⁶ The therapy of the disease is symptomatic and may include steam inhalation, codeine, aspirin, bed rest, and adequate fluid intake.

LABORATORY DIAGNOSIS

Reliable laboratory test procedures have been developed for diagnosis of infection with the Adenoviruses.^{10,13,28} These involve either (a) the demonstration of a significant increase in amount of complement-fixing (CF) or neutralizing antibody against the virus in the patient's serum during the progress of the disease or (b) the recovery and identification of the causative agent. Antigen employed for performance of the CF test is prepared from tissue cultures infected with an Adenovirus, usually RI-67.^{10,28} The "soluble" antigen active in such material is sufficiently group-specific so that antigen prepared from a single type will suffice to detect infection with any of the known types.^{11,13,28} The demonstration of a fourfold or greater increase in CF antibody in the patient's serum during convalescence (two weeks after onset) as compared with the acute phase specimen is considered to be of diagnostic significance. For serodiagnosis by the neutralization procedure, the titer of viral "inactivating" antibody in the acute and convalescent (three weeks after onset) serum samples is determined in tissue cultures. As in the CF test, a fourfold or greater increase in antibody level is diagnostic, but a "battery" of different serotypes must be employed because the serologic response in most patients usually is markedly type-specific against the homologous infecting strain.

At the present time, types 3, 4, and 7 virus appear to suffice for diagnosis of the military cases.^{11,21} The majority of the cases reported in civilian groups are type 3.^{17,24,25} For virus recovery attempts, the patient's throat washings are inoculated into appropriate human cell tissue cultures and the recovered agents are identified in neutralization or CF tests with known positive anti-

sera. Virus usually can be isolated from 25 to 50 per cent of all patients who have Adenovirus illness proved by serologic procedures. The virus recovery and serum neutralization tests, which must be carried out in tissue culture, are necessarily laborious and expensive and are therefore limited to research laboratories. The relatively simple *in vitro* CF test, on the other hand, is best suited for routine diagnosis where the identification of the particular infecting type is unnecessary.

EPIDEMIOLOGY

Respiratory illness caused by the Adenoviruses is widespread in military populations, primarily among newly inducted soldiers.^{10, 11, 12, 17, 21, 22, 27, 28} The illness is far less common among "seasoned" troops than in recruits.^{17, 29} The disease occurs in epidemic form throughout the year but is most prevalent during the winter months, when it may account for as many as 9 of every 10 hospitalizations for respiratory illness in recruit training camps.^{22, 27, 29} This occurrence in all seasons is in striking contrast to that of influenza, which is epidemic only during the winter and is seldom encountered during other times of the year. The year-round prevalence of Adenovirus infections indicates that the virus resides continuously in the human population and that at least one means for perpetuating the disease is by contact with patients. The epidemic pattern²⁹ of outbreaks of Adenovirus respiratory disease in individual companies of soldiers during a period of high prevalence in the camp is, like that of influenza, explosive in nature, having reached the peak by the third week after the men were inducted into the Army. The over-all occurrence of the disease on the post, however, appears as a continuous curve which is a summation of the series of outbreaks in the individual training companies.

The importance of respiratory illness caused by the Adenoviruses to the armed services is reflected in the high proportion of soldiers who develop the clinical disease during their basic training period. The findings of a recent study²⁹ of the incidence of Adenovirus infections among recruits made at Fort Dix, N. J., indicate that approximately 80 per cent of the recruits who took their basic training at this post during the winter of 1954 acquired Adenovirus infection during their first 8 weeks in the Army and only 20 per cent escaped without infection. The Adenovirus infections acquired during this period were almost equally divided between recruits who manifested clinical respiratory disease and those who had inapparent infections or illness so mild that the soldier did not seek medical care. Among those who became sick, roughly half had an illness severe enough to require hospitalization while that of the remaining individuals was relatively mild and was treated on an outpatient basis at the dispensary. Similar studies of recruits who received their basic training

in the summer showed that a much smaller percentage acquired Adenovirus infections and only 10 per cent became infected. The relative proportion of patients who were hospitalized with mild or inapparent cases, however, remained roughly the same as during the winter months.

Further investigations by our group to determine the economic importance of Adenovirus respiratory disease in military personnel were conducted by laboratory study of a representative sample of patients with acute respiratory illness hospitalized at Fort Dix, N. J., during the period from June 1954 through May 1955. During this time, approximately 15,000 admissions were recorded, of which about 10,000 were for respiratory disease. Based on the laboratory test results, about 60 per cent of the recruit respiratory disease, or an estimated 6,000 cases, were caused by the Adenoviruses. The hospital stay for such patients may average around 10 days,^{16,17} thus resulting in about 60,000 days of hospital care and man-days lost. It has been estimated¹⁸ that the average cost per day for medical care in a station hospital such as Fort Dix is \$20.31 and the daily cost per man-day in the service during the first 25 weeks in the Army is \$14.65 (excluding the allowance for medical care). Based on these figures, the total cost of Adenovirus disease among the recruits in this single recruit training base at Fort Dix may be estimated to approximate \$2,000,000 per year. Added to this are the costs for repeat training and such less tangible factors as the burdens imposed by disruption of the troop training program.

Even though the viruses of the Adenovirus family comprise at least 14 distinct immunological types, only 3 of these, types 3, 4, and 7, have been found important in military populations.^{14,21} Among the cases, roughly 40 per cent appear to be caused by type 4, 40 per cent by type 7, and only 20 per cent by type 3 virus. These findings are in marked variance with those found in civilian populations, in which type 3 has been predominant and types 4 and 7 only rarely encountered.^{17,24,25} The reason for this difference between military and civilian groups is not known.

PREVENTION

The economic importance of acute respiratory illness caused by the Adenoviruses to the military in time of peace and its more serious consequences during periods of mobilization for war make it expedient that some method be developed for its prevention. Studies to develop an effective Adenovirus vaccine have been in progress in several laboratories. Huebner and associates²¹ have reported that volunteers injected with a heat- or formalin-treated preparation of type 3 virus grown in tissue culture developed neutralizing antibody against the agent. Further, this vaccine afforded significant protection against the experimental

disease which resulted from challenge with type 3 virus onto the conjunctivae of the volunteers.

Recently, our laboratory at the Walter Reed Army Institute of Research recorded the development, preparation, and field evaluation of a formalin-killed Adenovirus vaccine prepared from monkey kidney tissue culture.²² This vaccine contained the two Adenoviruses, types 4 and 7, found predominantly in the military setting. It proved highly effective in the prevention in recruits of acute respiratory illnesses caused by the Adenoviruses.

The field evaluation of the vaccine was made at Fort Dix during the winter of 1955-1956, at a time when more than 90 per cent of all cases of respiratory illness in hospitalized recruits were caused by the Adenoviruses and when the predominant virus types were 4 and 7. The findings (fig. 1) showed, as might be

Figure 1. Relation of hospitalizations for acute respiratory illness to time of vaccination.

expected, that the vaccine did not prevent illness during the first week after vaccination. However, during the second, third, and

fourth weeks following vaccination, the incidence of respiratory illness in the vaccinated group was only one eleventh of that in the nonvaccinated controls. After the fourth week, the incidence fell to low levels, and no significant difference was found in the incidence in the vaccinated and control groups. By giving the vaccine as soon as possible after recruits are inducted into the Army, it should be possible to prevent most of the respiratory disease caused by the Adenoviruses which, as previously noted, occurs during the first four weeks of basic training." It should be noted further that most of the cases of acute respiratory disease which occurred among the vaccinated persons were not caused by the Adenoviruses. More recently (unpublished) it was shown that the vaccine effected a 98 per cent reduction in cases caused by Adenovirus specifically.

REMARKS

The discovery of the Adenoviruses (RI-APC-ARD agents) has taken a good-sized bite from the "respiratory pie," and the development of the effective vaccine shows promise of eliminating acute respiratory illness caused by the Adenoviruses as an important problem in military medicine. It should be pointed out, however, that there still remains a large bulk of acute respiratory illnesses of man of unknown cause. The continued application of human cell tissue culture to this problem should lead to the elucidation of the causes and eventual control of other respiratory diseases, the causation of which is presently unknown.

TOXIC EFFECTS OF CHLORPROMAZINE

Hepatitis and Agranulocytosis

WALLIS L. CRADDOCK, *Lieutenant Colonel, MC, USAR*

IN ADDITION to the milder side effects of chlorpromazine (Thorazine, Largactil), serious reactions may occur. Because of the hazards involved and the seriousness of the hepatitis and agranulocytosis that may result, it is essential that the present status of these events be reviewed.

CHLORPROMAZINE JAUNDICE

Enough well-documented cases of intrahepatic cholestatic jaundice from chlorpromazine have now been recorded to establish definite conclusions regarding the association of obstructive jaundice and the drug. A summary of earlier reports (through 1955) supported by liver biopsy and liver function studies appears in table 1. These cases illustrate the varied aspects of the problem. Of course, many more reports of probable chlorpromazine-induced jaundice have been published, but most of these have not been satisfactorily studied to rule out the possibility of concurrent exposure to other hepatotoxic or icterogenic agents or conditions. Laparotomy was performed in the earlier reported cases when the relationship of the drug to the jaundice was not clearly understood. The differential diagnosis is no longer as difficult, since the characteristic histopathologic features in this type of jaundice are now established and eosinophilia is often a companion finding. The lesion resulting from chlorpromazine administration is unlike that encountered in the livers of patients developing jaundice from external biliary obstruction. Evidence of stasis of bile is invariably found in the central portions of the hepatic lobules, whereas in jaundice resulting from external biliary obstruction, plugs of bile pigment may be found in any portion of the lobule, including the periphery.¹

Determination of the serum aminopherase (transaminase) activity gives an index of liver cell injury, aids in ruling out the

Read before the joint meeting of the Section on Gastroenterology and Proctology and the Section on Pathology and Physiology at the 105th Annual Meeting of the American Medical Association, Chicago, Ill., on 14 June 1956.

From Veterans Administration Hospital, Ft. Douglas, Utah. Col. Craddock is associated with 328th General Hospital, Ft. Douglas, Utah.

presence of viral hepatitis, and indicates impending liver failure. The fact that increased transaminase activity has been found to precede the development of jaundice resulting from chlorpromazine suggests that the transaminase test may be used as a tool to anticipate, and thereby prevent, toxic hepatitis in patients who receive this potentially hepatotoxic drug.³ This test appears to reflect the degree of hepatocellular damage more closely than the flocculation tests, serum cholinesterase and alkaline phosphatase activities, and other tests of liver dysfunction.

Although many chemicals are known to produce hepatic necrosis, the changes in the liver resulting from chlorpromazine administration simulate those seen in hepatitis induced by methyltestosterone and arsphenamine, with little or no evidence of hepatic cellular damage. Unlike other toxic injuries of the liver due to infectious agents (including viral hepatitis), halogenated hydrocarbons, and arsenic, hepatic injury resulting from chlorpromazine is usually mild, with minimal cellular degeneration and necrosis of individual central cells. There appears to be primary injury of the small biliary passages which become plugged with bile ("thrombi") and surrounded by an inflammatory exudate of polymorphonuclear leukocytes, eosinophils, and lymphocytes in the portal area.

It is interesting that the jaundice may occur several weeks after withdrawal of the drug,³ and icterus has lasted for seven weeks after only 50 mg of chlorpromazine was given.⁴ In cases of obstructive jaundice in which careful questioning of a patient discloses recent intake of even small amounts of chlorpromazine, operation should be deferred until a complete investigation is made to rule out the possibility of chlorpromazine-induced icterus. When cholelithiasis and cholecystitis are recorded in the history, it would be well to avoid the use of chlorpromazine because of the possible diagnostic confusion that may ensue in the hypersensitive patient. Although the jaundice may persist for over six months after drug withdrawal,⁵ there appears to be no residual hepatocellular damage, but further study may alter this view. Several clinicians believe that there may be a greater susceptibility to jaundice in patients with histories of liver disorders. In some cases the drug has been restarted without recurrence of the jaundice, but it is inadvisable to again give the drug. Sparine (brand of promazine) can be given if a patient has previously been sensitive to chlorpromazine, as jaundice attributable to the administration of this newer phenothiazine compound has not been seen.

Although the seat of the reaction appears to be in the portal area, experimental evidence strongly suggests that the drug produces stasis in the biliary tree due to an increase in the resistance of the choledochoduodenal sphincter,⁶ thus depressing

TABLE 1. Summary of reports of chlorpromazine jaundice supported by liver biopsy and liver function studies (1954-1955)

Author	Case no.	Chlorpromazine		Maximum serum			Eosinophilia (per cent)	Weeks of icterus	Remarks
		Daily dosage (mg)	Duration of treatment (days)	Bilirubin (mg/100 ml)	Alkaline phosphatase (B. U.)	Cholesterol (mg/100 ml)			
Lemire & Mitchell ¹⁴	1	200	23	(Ict. Ind. 106)	17.3	-	7	6	Laparotomy done in all 3 cases. All had severe pruritis but no chills, fever, vomiting, or malaise.
	2	100	15	48.6	10.8	250	17	8	
	3	50	31	8.1	36.0	584	Absent	6	
Boardman ¹⁵	4	Up to 500	21	23.0	25.0	-	Absent		Death. Autopsy findings supported diagnosis of "toxic hepatitis."
Zatuchni & Miller ²⁰	5	75	14	13.7	10.0	461	Absent	4	Laparotomy.
Movitt, ¹² et al.	6	100	28	21.0	13.0	325	Absent	3	Laparotomy.
	7	50	30	26.0	32.0	610	Absent	6	Needle biopsy. Transient splenomegaly present.
	8	125	22	6.7	20.0	304	Absent	2	Needle biopsy.

TABLE 1. Summary of reports of chlorpromazine jaundice supported by liver biopsy and liver function studies (1954-1955)—Continued

Author	Case no.	Chlorpromazine		Maximum serum				Eosinophilia (per cent)	Weeks of icterus	Remarks
		Daily dosage (mg)	Duration of treatment (days)	Bilirubin (mg/100 ml)	Alkaline phosphatase (B. U.)	Cholesterol (mg/100 ml)				
Sussman & Sumner ⁴	9	50 (single dose)	-	14.0	9.0	-		Absent	7	Needle biopsy. Apparent acute hypersensitivity; 2 hours after repeat dose of 38 mg, severe systemic symptoms with recurrence of jaundice.
	10	75	21	18.8	16.6	276		42; 6 after 13 days	11	Needle biopsy; no response to ACTH therapy.
Gold, et al. ⁹	11	75	21	10.0	24.0	539		16	3	Needle biopsy.

duodenal motility. That jaundice is apparently not the result of direct toxic action of chlorpromazine on the liver⁷ is supported by the demonstrated lack of correlation between the amount of drug ingested and the occurrence of jaundice, the absence of liver damage in patients who have taken large amounts of the drug in suicidal attempts, the failure to induce liver damage in experimental animals, and the observation that in some patients jaundice is not apparent until some time after the drug is stopped.

The cause of the transient eosinophilia (as high as 42 per cent) is unknown. We have observed eosinophilia in several patients receiving chlorpromazine who did not develop jaundice, but one patient became jaundiced after eosinophilia had been present for about one week. Steroid or corticotropin (ACTH) therapy does not appear to affect the clinical course of chlorpromazine jaundice, in contrast to the prompt and striking response to intravenous ACTH therapy often demonstrated in cases of cholestasis of viral origin.⁸ Concomitant administration of other drugs such as large doses of estrogens and Atabrine (brand of quinacrine hydrochloride) might predispose to liver damage from chlorpromazine.

Jaundice occurs in about one per cent of patients treated with chlorpromazine in mental hospitals. Usually they are not very sick, and they experience less fatigue than patients suffering from other forms of hepatitis. Nevertheless, it must be emphasized that there have been several fatal cases of hepatitis implicating the drug. The jaundice may develop insidiously or there may be an abrupt onset of mild flulike symptoms with or without fever. A program of bed rest and special diet is unnecessary. Despite the hepatitis, electroconvulsive therapy has been given during the period of jaundice without any apparent ill effects. The liver is usually slightly enlarged but nontender. Transient splenomegaly has been reported. The results of the liver function tests are similar to those obtained in patients with obstructive jaundice, with significant elevation of serum alkaline phosphatase and transaminase activity and often high values of serum total cholesterol. The alkaline phosphatase may remain high after the serum bilirubin and cholesterol return to normal. A very high cholesterol level was reported in one case (1,768 mg per 100 ml); in this instance the hyperlipemia may have been due in part to the diabetes and renal disease that complicated the hepatitis.⁹ However, the serum cholesterol returned to normal after the jaundice disappeared. There has been no evidence of disturbed porphyrin metabolism from chlorpromazine in the cases we have studied.

Another interesting observation is the elevation of blood urea nitrogen recorded in 8 of 12 cases reported by Kelsey and associates,¹⁰ the levels ranging from 20 to 130 mg per 100 ml. In one

patient known to have azotemia at the time of drug administration, the blood urea nitrogen rose from 60 to 130 mg per 100 ml in a two-week period. During this time he developed jaundice. This suggests the possibility that impaired renal excretion of the drug might play some role as a cause of hepatic injury.

Because evidence of functional hepatic impairment in patients on chlorpromazine therapy has been demonstrated by liver tests in the absence of jaundice (in 50 per cent of the cases reported by Lehman and Hanrahan¹¹), it may be wise to carry out such laboratory procedures in all patients receiving large doses of the drug over prolonged periods.¹² In one study³ 100 patients treated with chlorpromazine were followed by serial determinations of the alkaline phosphatase activity. The drug was discontinued when the concentration exceeded normal. In this group only one patient developed jaundice.

A review of the cases of jaundice due to chlorpromazine reported in the literature through 1955 reveals the data to be rather inadequate for excluding the possibility of concurrent exposure of the patient to other hepatotoxic or icterogenic agents and conditions. Criticism pertains particularly to the cases in which no histopathologic studies were done. Five cases of chlorpromazine jaundice have been carefully studied at our hospital. The transaminase activity in all cases followed the pattern seen in extrahepatic obstructive jaundice. The electrophoretic pattern of the serum proteins was undisturbed. In one case jaundice did not appear until three weeks after the drug was stopped; a total dose of 1.1 grams of chlorpromazine had been given in a dosage of 0.25 gram daily.

The laboratory data in one of our cases are summarized in table 2. All cases have been followed in similar manner. The histopathology report of a biopsy specimen of the liver in this case was: "Periportal area shows minimal fibrosis with lymphocytes, eosinophils, and polymorphonuclear leukocytes. There is also a mild focal necrosis of some periportal hepatic parenchymal cells. Some sections disclose inspissated bile plugging tiny canaliculi. Proliferation and distortion of small bile ducts are evident." Biopsies of liver specimens performed in the other cases showed similar findings.

An additional patient was studied at another hospital.¹³ Jaundice began more than three weeks after stopping chlorpromazine; only 0.025 gram of the drug was given daily for six days. Serum bilirubin was 14 mg per 100 ml and alkaline phosphatase was 34 Bodansky units when laparotomy was done, although blood eosinophilia of 32 per cent suggested drug-induced icterus. No gross pathologic lesions were seen at operation, but a biopsy specimen of the liver showed the characteristic features described in chlorpromazine hepatitis.

TABLE 2. Laboratory data: Case report of chlorpromazine jaundice*

Year 1955	12-8	12-12	12-14	12-16	12-19	12-21	12-23	12-27	12-30

Porphobilinogen	neg	neg		neg		neg			
Serum amylase (control) in units			354 180		304 156		180 156		

*Liver biopsy performed on 12-12-55.

X-ray chest (12-8-55), flat plate of abdomen (12-12-55), and cholecystogram (12-19-55): all normal.

Urinalysis remained within normal limits except for bilirubin; hct. bleeding time, coagulation time, prothrombin activity, electrocardiogram: all normal. Fasting blood sugar (true), 80 mg/100 ml; blood urea nitrogen, 11 mg/100 ml (12-12-55).

AGRANULOCYTOSIS FROM CHLORPROMAZINE

The possibility that patients treated with chlorpromazine may develop agranulocytosis is not as widely appreciated as it should be, since this serious complication occurs much more seldom than chlorpromazine jaundice. Fever, jaundice, and skin eruptions during the early weeks of treatment should be taken as danger signals and compel repeated examination of the blood, if not withdrawal of the drug.

Ulcerative stomatitis, particularly if it occurs at about the sixth week of treatment, should be an absolute indication for the immediate cessation of therapy.¹⁴ One case concerns a patient in whom jaundice was followed by agranulocytosis and death.¹⁵ A causative relationship in this case between the administration of chlorpromazine, subsequent jaundice, and agranulocytosis can only be assumed. The circumstantial evidence, however, is strong in view of accumulating reports. The earlier reports are summarized in table 3.

The mechanism of the production of agranulocytosis and the therapeutic approach to this disorder are discussed in a review by Rotstein, Frick, and Schiele.¹⁶ It is suggested that chlorpromazine agranulocytosis occurs within eight weeks after the drug is started, and most cases to date have occurred in patients over 50 years of age. Unpublished reports of agranulocytosis attributed to use of chlorpromazine total more than 50 cases with at least 17 deaths.¹⁷ At the rather alarming rate these cases are accumulating, the drug may come to rank as an offender comparable to chloramphenicol, the thiourea derivatives, several antiepileptic drugs, and many other new drugs known to cause fatal agranulocytosis.

SUMMARY AND CONCLUSIONS

A study has been made of the better documented reports of chlorpromazine jaundice and agranulocytosis. The important features of these complications have been reviewed.

Chlorpromazine-induced jaundice is of the intrahepatic cholestatic type, and there is usually no associated hepatocellular damage. Nevertheless, several deaths from chlorpromazine hepatitis have been reported. Since the clinicopathologic syndrome of primary intrahepatic cholestasis may have diverse causes, the jaundice may offer considerable difficulty in differential diagnosis. Jaundice may occur several weeks after discontinuing the drug, and it may persist for many months, irrespective of the amount of drug given. In cases of obstructive jaundice in which careful questioning of the patient discloses recent intake of even small amounts of chlorpromazine, operation should be deferred until a complete investigation is made to rule out the possibility of drug toxicity. The transaminase test is valuable in excluding

TABLE 3. *Agranulocytosis associated with chlorpromazine administration (1954-1955)*

Author	Case no.	Chlorpromazine			Lowest white blood cell count	Differential (per cent)	Bone marrow examination	Remarks
		Daily dosage (mg)	Total dosage (grams)	Duration of treatment (days)				
Boleman ²⁴	1	280	6.0	60	500	100 leukocytes	Aplastic marrow	Death 2 days after onset of diarrhea, fever to 105°F, increasing pulmonary edema. (Small doses of phenobarbital had also been given. A few cases of agranulocytosis from phenobarbital have been reported.)
Hodges & LaZerte ¹⁵	2	50	1.4	28	4,900	99 leukocytes 1 monocytes	Hypocellular	Death. Exploratory laparotomy one week prior to death because of possible "surgical" jaundice. Biliary tract and adjacent organs normal. Liver biopsy characteristic of chlorpromazine hepatitis. ACTH given after onset of jaundice and prior to agranulocytosis without benefit.
Lomas ²⁵	3	250-300	6.0	21	680	89 leukocytes 11 neutrophils	Not done	Recovery after 5 days. Cortisone used in addition to antibiotics.
Munch-Petersen ²⁶	4	200-250	10.8	48	800	86 leukocytes 14 neutrophils	Not done	Recovery after 9 days.

TABLE 3. *Agranulocytosis associated with chlorpromazine administration (1954-1955)*—(continued)

Author	Case no.	Chlorpromazine			Lowest white blood cell count	Differential (per cent)	Bone marrow examination	Remarks
		Daily dosage (mg)	Total dosage (grams)	Duration of treatment (days)				
Glacchini & Laseenius ²⁷	5		Not stated		900	78 leukocytes 22 neutrophils	Not done	Recovery after 40 days.
Tasker ¹⁴	6	75-150	5.5	41	900	95 leukocytes 5 neutrophils	Not done	Death. Clear-cut clinical evidence of chlorpromazine sensitivity (erythema and rash) preceded agranulocytosis by 2½ weeks. No autopsy.
Prokopowycz ²⁴	7	100-150	5.8	50	1,500	79 leukocytes 20 monocytes 4 myelocytes 6 neutrophils	Not done	Death in 36 hours after onset of agranulocytosis. No autopsy.
Rotstein, Frick, & Schiele ¹⁶	8	75-100	4.0	50	350	100 lymphocytes	Hypocellular with virtual absence of granulocytes	Complete recovery with normal bone marrow 19 days after onset of symptoms. Fall in hemoglobin from 16.0 to 10.8 g/100 ml within 6 weeks after drug started.

the possibility of concurrent exposure of patients to other hepatotoxic or icterogenic agents or conditions. Increased transaminase activity has been found to precede the development of jaundice from chlorpromazine.

During the first two months of therapy it is recommended that a urinalysis be done for bile twice a week, and that frequent white cell counts be made during this period and whenever else indicated, especially when fever, sore throat, or skin eruption suggests the presence of sensitivity to the drug. If the blood serum appears icteric, serum bilirubin, alkaline phosphatase activity, and other liver function studies are indicated, as all cases of toxic reactions should be carefully studied. However, no laboratory data can be substituted for careful, continued, clinical observation of the patient.

It would seem wise to avoid chlorpromazine therapy when infectious hepatitis is endemic, in the presence of liver disease, in malnourished patients, and when other potentially hepatotoxic agents have been used. Sparine (brand of promazine) can be safely given if a patient has previously been sensitive to chlorpromazine.

RESENTMENT TO ANTIBIOTICS

To those of us who, like Ambrose Pare, believe in the fundamental normalcy of the healing processes in man when tissues are tenderly handled and left so far as possible in their natural state, there is neither need nor justification for the surgeon routinely to divide the responsibility for an intestinal anastomosis between his surgical skill and the antibiotics. We may even wonder if the reaction, mild or fatal, which occasionally follows the use of these agents may not suggest resentment on the part of the body to their interference with a function which it is so well devised to carry out.

PSYCHOLOGICAL COMPARISON OF AUTOMOBILE DRIVERS

Accident- and Violation-Free Versus
Accident-Violation-Incurring Drivers

FREDERICK L. MCGUIRE, *Lieutenant, MSC, USN*

THE PROBLEM of highway safety, because of the thousands of lives and billions of dollars expended each year in automobile accidents, is one of our foremost social problems. Adequate descriptions of this carnage and waste appear elsewhere.¹⁻³

The concept of unequal liability⁴ (often referred to as accident proneness) prompted a widespread search for factors which make one person more liable to accidents than another. Most of the earlier studies were concerned with psychophysics, investigating such factors as vision, hearing, reaction time, and co-ordination. More recent research, dealing primarily with sociologic and personality factors as possible correlates of accident frequency,⁵⁻⁸ has made it apparent that psychophysical measurements of human performance are not adequate for accident prediction even though there are instances in which a statistical significance can be demonstrated.⁹

Previous investigations of personality and biographical factors as related to automobile accidents have likewise produced little evidence that is conclusive in itself, because they were not always carefully controlled. The findings were of enough significance, however, to indicate that this approach to the problem might be fruitful.⁵⁻⁸ In nearly all of this work a basic difficulty in methods was encountered. Analyzing the many personal and situational factors that must take place in exact sequence for an accident to occur becomes an extremely complex problem. The statistical manipulation of these variables would be an impossible task, since many of them are intangible and cannot be measured adequately.

The hypothesis of accident proneness assumes that a significant number of people have qualities in common that predispose

them to accidents, and further assumes that these qualities are relatively stable and amenable to measurement. The limited success met by the use of objective-type measuring technics indicates, however, that accident-producing qualities either do not possess these two attributes, or that the technics employed have not been adequate. It would appear, therefore, that if we are to achieve success in differentiating automobile drivers, a new approach must be sought.

The emphasis in the study here reported falls upon the accident- and violation-free group in an attempt to outline personality traits uniformly present in accident-free individuals. There are four reasons why it is logical to study the safe driver rather than the accident repeater: (1) It is the safe driver we wish to select for taxis, buses, trucks, and other vehicles. (2) The accident repeater contributes not more than three to four per cent to the accident problem.¹⁰ (3) The safe driver is more easily defined operationally. (4) Many unsafe drivers do not fall in the accident-repeater classification. The experimental design of this study is based on the assumption that the accident- and violation-free driver belongs to a homogeneous group. That is, prolonged safe driving can be produced only by adhering to a common set of rules and regulations of conduct and therefore must be produced by drivers with similar attitudes and behavior patterns. On the other hand, a person may be accident-prone for as many reasons as there are patterns of maladjustment, and a particular member of the group need not bear any similarity to any other member except in terms of his accident record.

METHOD

Two groups of 67 subjects each, selected and carefully matched by methods previously described,¹¹ were compared in this study. One group was chosen from Camp Lejeune accident records and consisted of men each of whom had had at least one accident within recent months in which he had also violated a moving traffic regulation. The other group comprised persons whose answers to a questionnaire indicated that they had neither been involved in an accident nor been cited for a traffic violation of any type throughout their driving careers, and who in other ways matched the accident group.

Every subject in each group, as reported in detail previously,¹² received extensive psychometric testing plus a personal interview. From the results of the various tests given, the scores selected for analysis of differences between the two groups were those of the Minnesota Multiphasic Personality Inventory (MMPI), the Bell Adjustment Inventory (Bell), the Kuder Preference Record-Personal (Kuder), and the Rosenzweig Picture Frustration Study (Rosenzweig). These tests, plus the miscellaneous attitude

items, were subjected to item analysis, and the items that differentiated between the two groups by at least a 5 per cent level of confidence were examined for personality, sociologic, and attitude characteristics that would identify the accident- and violation-free driver. Items found to have no particular ability to describe traits of either group were not used in the interpretation.

RESULTS AND DISCUSSION

Table 1 lists those scales of the standardized tests that produced significant differences between the two groups. It is noted that two scales of the MMPI—the Psychopathic Deviate (PD) and the Schizophrenic (Sc)—were significant.¹¹ This does not mean that the accident group is psychopathic or schizophrenic simply because its score is significantly higher than that of the accident-free group; actually, the scores of both groups lie well within the normal range. It does lend support, however, to the hypothesis that personality tests of this type are capable of differentiating between accident-incurring and accident-free populations.

TABLE 1. *Results of test scales that differentiated between groups*

Test scale	Accident-free group		Accident group		Critical ratio
	Mean	S. D.*	Mean	S. D.*	
Minnesota Multiphasic Personality Inventory					
Psychopathic deviate	15.7610	03.9161	19.4630	04.4800	5.0539
Schizophrenic	08.7460	06.4440	12.0300	08.9363	2.4215
Rosenzweig Picture Frustration Study					
Ego-defensive	59.3000	11.1530	53.3000	10.1700	3.2290
Need-persistence	24.9000	10.3200	30.7000	09.4500	3.3680

*Standard deviation

The Rosenzweig showed significant differences on the Ego-Defensive (E-D) and Need-Persistence (N-P) scales.¹⁴ As with the MMPI scales, the evidence is not sufficient to allow more than speculation as to the meaning of these differences. This is especially true because the Rosenzweig is still in the process of being validated.¹⁵ If one examines the various possible types of response under these two scales, it becomes evident that it is not possible to conclude much about the mode of reaction to frustration for either group, or to infer personality dynamics. It was possible to obtain separate scores based on an item analysis of the Rosenzweig. When the two groups were scored on the basis of these items the scores produced a biserial correlation of 0.53 with the criteria. The results of this work were reported previously.¹¹

Item analysis disclosed that about 85 items from the Bell, MMPI, Fuder, and the collection of miscellaneous attitude items were significant to at least the 5 per cent level of confidence (c. r. of 1.96 or more). An examination of these items produced definite and consistent psychological patterns. Thus it became possible to describe some of the traits that tend to be associated with accident- and violation-free behavior on the highway.

When compared with the accident-violation driver, the accident- and violation-free driver shows the characteristics listed in the following tabulation. The figures in parenthesis after each item refer to corresponding items in the Safe Driver Inventory Test.¹¹

1. *Is more conservative and moderate in his attitudes*

- a. Less attracted to the use of alcohol. (21, 83)
- b. Less attracted to taverns and liquor parties. (79, 80)
- c. Does not like to see women smoke. (29)
- d. Goes to church more often and is more attracted to the church. (9, 81, 82)
- e. Prays more often. (33)
- f. Does not as readily agree that war is necessary under any conditions. (72, 73)
- g. Is more careful whom he trusts. (23, 24).
- h. Does not feel he has to bet on a race or game in order to enjoy it. (14)
- i. Is more concerned over his health. (2)
- j. Is less in favor of socialism. (86)

2. *Is socially more efficient*

- a. Has a greater liking for working with people. (55C, 57B)
- b. Has less difficulty dealing with groups. (70, 56B)
- c. Finds it easier to find interesting things to do. (1)
- d. Has a kinder attitude toward people. (61A)

3. *Is socially more stable*

- a. Doesn't feel like picking fights as often. (8, 10)
- b. Doesn't lose his temper as easily. (22)
- c. Is not as easily upset or apt to take every little thing to heart. (28)
- d. Is happier with his job. (66)

4. *Has more mature outlook*

- a. Isn't as quick to blame others for his troubles. (12, 15)
- b. Isn't as prone to cry over spilt milk. (67)
- c. Has fewer misgivings about the past. (5)

5. *Has different tastes and interests*

- a. Has greater liking for:
 - (1) Poetry. (5, 42B)

- (2) Growing plants and collecting flowers. (16)
 - (3) Reading history. (35)
 - (4) Attending lectures on serious subjects. (30)
 - b. Has less liking for:
 - (1) Attending exclusive night clubs. (54A)
 - (2) Dog and horse races. (42C, 85)
 - (3) Being an auto race driver. (31)
 - c. Has greater interest in education and science. (84, 88)
6. *Is more conscientious and ambitious*
- a. More willing to accept responsibility. (40C, 51A)
 - b. Can make decisions more easily. (18)
 - c. Has a higher aspiration level. (45C, 51C)
 - d. Sets higher workmanship standards for himself. (34)
 - e. Is not as easily influenced by other people. (8)
 - f. Is more concerned with his personal independence. (68)
7. *Had happier childhood*
- a. Had fewer arguments with his family. (10)
 - b. Had fewer impulses to run away from home. (27, 71)
 - c. Was happier and more productive in school. (3, 20, 26)
8. *Has healthier attitude toward law*
- a. Is more ready to believe law helps the common man. (77)
 - b. Has had less trouble with the law. (25)
 - c. Is more concerned with staying out of trouble with the law. (19)
9. *Has healthier attitude toward operating a vehicle on the highway*
- a. Doesn't believe accidents are mostly due to luck. (76, 78)
 - b. Believes a good driver must always pay close attention to his driving. (75)
 - c. Is more willing to share highway with trailer trucks and other vehicles. (74)

In addition to using the statistical method in choosing the significant items, two other criteria can be employed in order to test their validity. The first is to note whether or not there is any contradiction between test items. For example, there were several items concerning the school history and home life of the testee. If these items were chosen by chance only, it is likely that at one point the accident group would have indicated a happier school or home life, but in response to a similar item might have indicated the opposite. One of the two groups might have reported that they prayed more often, yet have indicated a less frequent church attendance; or they might have indicated a greater liking for liquor parties, yet have shown that they used alcohol to a lesser extent than the other group. The list of items chosen do not contain any such contradictions.

The second test is one of chance. Using the 5 per cent level of confidence as a criterion, it can be said that by chance

alone 5 out of every 100 test items would be chosen as being statistically significant. This presupposes that every item has as much chance of being selected as every other. Because of the heterogeneous nature of the different test items in the original pool and their uneven distribution, this prerequisite cannot be fulfilled. Therefore, if more than the expected number of items were selected as being significant it is a point in favor of the validity of the chosen items; however, if the number of items chosen was less than expected the evidence is not negative.

In general, the chosen items meet the second test, but I do not rely on it as an adequate test and am more inclined to accept the test of intra-item consistency. When these items were placed in test form and submitted to cross-validation groups similar to those used in this study, the results supported their validity.¹² Work done by other investigators also tends to support the conclusions drawn from them.

The characteristics of the accident-violation-free driver, as they have been outlined here, tend to lend themselves very well to that kind of driving behavior that is generally thought to be necessary for accident-free operation. In other words, the results are what one would expect. For example, we would certainly expect the safe driver to have a healthier attitude toward law. The fact that he is a more responsible person and is more conservative in his use of alcohol also logically fits the picture of a safer driver. The fact that he is more intellectually inclined and more at home with ideas equips him better to understand that traffic signs and laws are the attempt of society to protect itself—to understand that group living requires certain responsible behavior.

Because driving upon the highway is essentially an interpersonal situation, we would expect that the person who gets along best on the highway also gets along best with people. It is fitting that our accident- and violation-free driving group should bear the earmarks of better adjustment—a smoother home life and more ease in his relations with people.

Tillman's work agrees with what has been found in this study. Due to differences in the technics used, certain characteristics of the groups are emphasized more in this study than in Tillman's, and there are differences in the kinds of characteristics listed, but in no instance do Tillman's data contradict any of our findings. His high-accident population of taxi drivers is more extreme in their "undesirable" qualities; they seem to be borderline psychopathic deviates. This may be due to the type of population he used for the study and not be a true description of all high-accident drivers.

Tillman's data were gathered by interview technics. He spent three months in informal fashion with the drivers, riding in their

cabs and talking to them between fares. In spite of possible sources of bias (Tillman apparently knew in advance which drivers were in the high-accident and low-accident groups), the method used has the advantage of being able to handle and evaluate many variables at once and is limited only by the skill of the investigator. Unskilled or semiskilled persons cannot apply the technic, and the results do not permit objective analysis. The questionnaire method, as used in this study, is able to circumvent these two objections. Both methods have definite worth, and it is important to note that they yield similar results.

Work by Dunbar¹⁴⁻¹⁸ with hospital fracture cases, utilizing interview, biographic, and Rorschach data, arrived at conclusions compatible with the results of this study and of Tillman's. A preliminary report of work now being done at the University of Colorado¹⁹ indicates that its sample of drivers possess personality characteristics consistent with those reported herein.

SUMMARY AND CONCLUSIONS

Two groups of automobile drivers, each consisting of 67 subjects, were tested and interviewed. One group comprised drivers who in all their driving history had never incurred a motor vehicle violation or been involved in an automobile accident of any kind. The other group was composed of drivers who recently had been involved in at least one accident in which they had incurred a moving violation.

An item analysis of the test items (excluding the Rosenzweig and the sentence-completion test) provided a method of describing certain personality, sociologic, and attitudinal differences between the two groups. It was determined that the accident- and violation-free driver is more mature, conservative, and intellectual in his interests and tastes, has a higher aspiration level, and is the product of a happier family background than is the accident-violation-incurring driver.

RESEARCH AND THE PUBLIC

"Over the next decade, the public image of science, of medical research, and of the scientist may become more realistic. Research is more widely publicized through newspapers, magazines, radio, and television than at any time in the past. The public's avidity, spontaneous or artificially stimulated, for information on research is remarkable. The emergence of scientific writing for popular consumption as a clear professional journalistic specialty is a most encouraging development for the future. The development of a mature attitude by scientists toward their responsibilities and their rights in communicating to the public is another encouraging factor."

A STATISTICAL STUDY OF ALVEOLAR OSTEITIS

SAM R. ADKISSON, *Captain, USAF (DC)*

PERRY F. HARRIS, *Captain, USAF (DC)*

ALVEOLAR osteitis has consistently been the most unpleasant and the most frequent single complication following the extraction of teeth. A specific definition for alveolar osteitis (or "dry socket," as it is more commonly known) is lacking in the literature. The clinical entity most commonly diagnosed as alveolar osteitis is generally characterized by one or more of the following conditions: (1) pain, (2) loss of a normal blood clot in the socket, (3) denuded bone surfaces and necrotic material in the socket, (4) delayed healing, and (5) foul odor. A number of causative factors has been suggested and a variety of treatments used. It may be concluded that the cause or causes and mechanism of alveolar osteitis are not yet fully understood. This particular study has been undertaken in order to determine any relevant statistical patterns related to alveolar osteitis as observed among personnel of the U. S. Air Force.

MATERIAL AND METHODS

All data for this study were collected from AF Form 309, Dental Health Record, of U. S. Air Force personnel on active duty. A series of 5,500 consecutive clinical records was screened for recorded cases of alveolar osteitis. No distinction was made as to grade or rank of the patient in the collection of data.

In the series of 5,500 clinical records surveyed, there were found 116 (2.10 per cent) patients in whom alveolar osteitis had been diagnosed and treated. The distribution of cases by age of the patient is not considered significant, as the incidence seemed to be well spread over the age group of men in active military service who required extractions (table 1).

Considerable seasonal variation in the occurrence of alveolar osteitis was observed (fig. 1). The peak of occurrence was reached in March, following a rise through January and February. The month with fewest cases treated is June. Approximately 43 per

From U. S. Air Force Hospital, Brookley Air Force Base, Ala. Capt. Adkisson is now assigned to U. S. Air Force Hospital, Olmsted Air Force Base, Middletown, Pa.

TABLE 1. *Distribution of cases by age of patient*

Age	No. of cases	Age	No. of cases	Age	No. of cases	Age	No. of cases
19	9	28	6	37	1	46	0
20	7	29	6	38	0	47	0
21	4	30	7	39	1	48	0
22	9	31	4	40	2	49	0
23	13	32	3	41	1	50	0
24	7	33	2	42	2	51	1
25	4	34	2	43	1	52	0
26	7	35	3	44	0	53	0
27	5	36	8	45	0	54	1

cent of all cases occurred in the three months' period of January through March. This is usually considered to be the season in which general body resistance is at a low level and upper respiratory infections are active. That the incidence of cases occurring in December is lower is probably due to the fact that many servicemen are on leave and fewer teeth are extracted during this period.

Figure 1. *Distribution of cases by month of occurrence.*

No cases in conjunction with pericoronal infections in the upper arch were found in this study. All cases of pericoronal

infection studied were associated with lower third molars. Of the total of 51 such cases, 34 (66.7 per cent) were associated with previous pericoronal infection. This fact points up the importance of carefully controlling pericoronal infections before extracting lower third molars.

There is a marked predilection for alveolar osteitis as the tooth location becomes more posterior. The peaks of incidence are in the lower third molar areas (44.0 per cent) with lower molar and bicuspid areas next in order (fig. 2).

*The teeth are numbered 1 through 32, with No. 1 being the upper right third molar; No. 16 being the upper left third molar; No. 17 being the lower left third molar; and No. 32 being the lower right third molar.

Figure 2. Distribution of cases by location of tooth involved.

The removal of lower teeth much more often results in alveolar osteitis. About 84 out of every 100 cases are in the lower arch (table 2). The variation in occurrence between right and left sides is not considered significant.

Alveolar osteitis more often follows a single extraction than a multiple extraction. Of all cases studied, 80.2 per cent were associated with a single extraction. Surgical removal was performed in 34.5 per cent of all extractions, and in 58.8 per cent of extractions in lower third molars. Trauma, therefore, may not

be as important in causing alveolar osteitis as hitherto believed. Sutures were used for closure in 44.8 per cent of the cases studied. The variation between these cases and those in which sutures were not used is not considered significant.

TABLE 2. *Distribution of various findings in 116 patients with alveolar osteitis*

Findings and occurrence		Number of cases
Location	Arch	
	Upper	19
	Lower	97

	No	78

POSTOPERATIVE PERIOD

The period of time elapsing between extraction and the institution of treatment for alveolar osteitis varied with the individual case (fig. 3). The number of patients returning for treatment rose from the first postoperative day to a peak on the fourth postoperative day. In 70.7 per cent of all cases, treatment was begun by the end of the fourth postoperative day. By the end of the first postoperative week, 95.7 per cent of all patients had returned for treatment.

Figure 3. Distribution of cases by postoperative day on which treatment was begun.

The number of days' treatment required varied with the individual case (fig. 4). The peak number of cases was completed by the end of five days of treatment. By the end of one week of treatment 60.3 per cent of all cases were completed. By the end of two weeks of treatment, 87.1 per cent of all cases were discharged without further treatment. A few resistant cases required treatment for from three to four weeks.

Figure 4. Distribution of cases by the number of days' treatment required.

The prescription of sedatives or hypnotics to control pain and/or induce sleep varied with the needs of the individual patient. Of the cases herein reported, 82.7 per cent required no medication other than the local treatment of the affected socket (table 2). There seems to be no uniformity of opinion among dentists as to the efficacy of systematically administered antibiotics in the treatment of alveolar osteitis. Of the patients studied only 19.0 per cent were given antibiotics as a part of treatment. The sample reflected in this survey on this point is not sufficiently great to justify any conclusions. About 33 per cent of the patients considered in this study had previously been treated for alveolar osteitis. This seems to indicate that certain patients have a greater tendency to develop an alveolar osteitis than do others.

Although the interrelation of the various dental diseases is not well understood, there appears to be a direct correlation between the incidence of alveolar osteitis and other forms of dental disease, with osteitis tending to occur in mouths where other diseases are active. The 116 subjects of this study who had alveolar osteitis also had, on the average, 2.3 decayed, 6.0 missing, and 7.7 filled teeth.

CONCLUSIONS

A statistical study of alveolar osteitis has been presented in which the incidence of this postoperative complication has been correlated with reference to a series of some 15 variables. It may be concluded that alveolar osteitis does follow certain patterns within limits as described. The whole subject of alveolar osteitis is deserving of further study in order that our methods of prevention and treatment be improved.

CARCINOMA OF THE BREAST

More than 16,000 women die annually of carcinoma of the breast in the United States, and its incidence is increasing at the rate of one percent. However, the present outlook is not so discouraging when it is realized that 10,000 of the deaths could be prevented if the disease were treated in the early stages. The education of women to a correct method of examination every month and emphasizing the necessity of reporting to their physicians every six months, or at any time a suspicious lesion occurs, is a big step forward.

of Surgeons*, p. 42, Jan. 1954

THE QUANTITATIVE INTERPRETATION OF BALLISTOCARDIOGRAMS

A New Approach

DONALD C. FISCHER, *Captain, USAF (MC)*

CARLTON L. SHMOCK, Jr., *Captain, USAF (MC)*

BALLISTOCARDIOGRAPHIC interpretation continues to suffer from the lack of a truly objective basis for analysis. As the subjective element infiltrates the evaluation, there is considerable variation in the final grading of any tracing. The frequency with which disagreements in interpretation arose in our clinic prompted the development of a grading system whereby a relative number of points are assigned to each abnormal constituent of the complexes. This point system of evaluation greatly reduced the subjective error which produced most of our discrepancies.

MATERIAL AND METHODS

The machine used in this clinic is a direct photoelectric ballistocardiograph employing an electrical filter to eliminate respiratory swing, recording through a photographic electrocardiograph equipped with an R wave injector.

Two hundred tracings from men found physically acceptable for military service were used to determine normal values for the length of the I-J segments. The lengths of I-J in inspiration and expiration were determined separately.

Our determined mean for I-J in inspiration was 10.1. The median was 9.5. Standard deviation determined from the sine curve plotted was ± 2.75 .

Similar measurements for I-J in expiration gave a mean of 7.5, a median of 7.0, and a standard deviation equal to ± 2.1 .

The importance of these determinations is discussed below.

METHOD OF GRADING

We consider the following in evaluating a ballistocardiogram:

1. Time of onset of H wave after R wave

From U. S. Air Force Hospital, Travis Air Force Base, Calif. Dr. Fischer is now at 3294 North Bend Road, Cincinnati, Ohio.

2. Time of occurrence of J peak after R wave
3. Respiratory variation in the lengths of I-J segment
4. Lengths of I-J in inspiration and expiration
5. Height and configuration of H wave
6. Depth and configuration of I wave
7. Configuration of J wave
8. Depth and configuration of K and M waves
9. Height of L and N waves

Normal variations of each of these factors were determined by our own experience and the reported findings of others. As suggested by Starr,¹ it was necessary to determine the limits of normal for length of I-J segments for our own particular type of machine (see above).

The following are considered abnormal for each component:

1. Onset of H wave more than 0.04 second after the R wave
2. Peak of the J wave less than 0.20 second or more than 0.26 second after the R wave
3. A variation of more than 50 per cent between the tallest and shortest I-J segment
4. An I-J in inspiration less than 7.5 mm in length or an I-J in expiration of less than 5.5 (for males)*

Points assigned each abnormality are relative to the importance of that portion of the cardiac cycle which the component represents. Points are assessed against a single component only once, regardless of the number of complexes in which it is abnormal (*e. g.*, 1 point is assessed if H is abnormal in all complexes or only in expiration).

1. Abnormal H timing	1 point
2. Abnormal J timing	1 point
3. Abnormal respiratory variation	2 points
4. Small I-J in inspiration	4 points
Small I-J in expiration	2 points
5. Abnormal H waves present	1 point
6. Abnormal I waves present	1 point
7. Abnormal J waves present	1 point
8. Abnormal K or M waves present	1 point each
9. Abnormal L or N waves present	1 point each

The final grade assigned any tracing is determined by the addition of the points assessed, thus:

Normal	not more than 1 point
Grade I	2, 3, or 4 points
Grade II	5 or 6 points
Grade III	7 or more points

*The exact range of normal for I-J segments of females is presently being determined.

Grade IV tracing so bizarre that
 waves cannot be identified
 for measurement

DISCUSSION

The grading of ballistocardiographic tracings by this method was compared with those involving the determination of the percentage of abnormal complexes. Four hundred tracings were originally graded by the method of Brown, Hoffman, and de Lalla,² prior to the adoption of the point system in our clinic. These were then re-evaluated according to the point system.

In 78 per cent of the tracings which were cross-graded, there was no change in the assigned grade. As was expected, *no* tracing which was *seriously* deranged improved in grade by any method of evaluation. For example, no Grade IV tracings were upgraded, and only rarely was a Grade III considered to be Grade II.

Of the records, 16.8 per cent were given an improved grade by the point system. The tracings in this group created the most arbitration in our clinic. They consisted primarily of tracings given a poorer grade by percentage determination of normal. For instance, an I to J ratio less than 1:2 or a tall H wave made it necessary to consider many otherwise normal complexes as being abnormal. Usually these tracings were taken from persons in excellent physical condition as determined by history, physical examination, and laboratory aids. We, therefore, felt justified in assuming that the point system had allowed us to classify these tracings more correctly.

Some 5.2 per cent of the tracings were given a lower grade by our method than had been determined by other methods. These were mainly recorded on males over the age of 40 years. The difference in evaluation resulted from the fact that although the tracing had a regularly recurring pattern and an I to J ratio of 1:2, suggesting a grade of normal, the I-J segments were abnormal according to our standards for I-J segment length. This is a common finding in tracings from persons beyond the fourth decade of life. However, the fact that it is common does not justify a classification of normal for this age. We are in agreement with Dock, Mandelbaum, and Mandelbaum³ when they state, "Abnormal patterns in the electrocardiogram or in the ballistocardiogram result from abnormal states of the circulatory apparatus, whether the individual is young or old."

The short I-J segments in all age groups primarily suggest degeneration of the myocardial thrust and a compromise in the efficiency of the heart as a pump. We feel, therefore, that this type tracing was not normal and should have been graded 3...

SUMMARY AND CONCLUSIONS

In our clinic frequent disagreements arose in interpreting ballistocardiographic tracings using the percentage of abnormal complexes as a criterion for grading. We therefore devised a point system of grading to help eliminate the subjective element. The point system is discussed, including our standards for I-J segment length in inspiration and expiration.

Four hundred tracings originally graded by the method of Brown, Hoffman, and de Lalla were re-evaluated by the point system. In 78 per cent of the tracings the grade was not changed, in 16.8 per cent the grade was improved, and in 5.2 per cent the tracing was downgraded. The reason that a change in grade by the point system seemed warranted is discussed.

The point system of grading which we have presented has been a substantial aid in developing better quantitative interpretations of ballistocardiograms in this clinic. It has been outlined here in the hope that it may benefit others who have had similar difficulties.

MISINTERPRETATION

Misinterpretation of what the doctor says is so easy for the patient. Many a doctor who has given an explanation on which he prides himself would be disconcerted to learn the retailed version of his carefully chosen words. That is why lucidity is so essential. It is a difficult art to cut one's explanatory coat according to the intellectual cloth provided by the patient, and it must be especially hard for psychiatrists to word their interpretations without ambiguity, because the mind is even harder to explain than the body.

CLINICAL RECOGNITION OF EARLY AND INSIDIOUS SCHIZOPHRENIA

JOHN W. BURKETT, *Lieutenant Colonel, MC, USA*

EARLY or insidious schizophrenia is not always obvious, even to the experienced psychiatrist, because it may simulate any psychiatric disorder and many organic illnesses.^{1,2} The resultant need to stress certain clinical features of schizophrenia became apparent to me through teaching psychiatry to general medical officers at this school and supervising the work of psychiatrists of limited clinical experience.

Although generally slighted in standard textbooks of psychiatry,³⁻⁵ the clinical features discussed in this article have been found to be of special value in detecting early and insidious schizophrenia, as distinguished from "pseudoneurotic schizophrenia," first described by Hoch and Polatin.⁶ Although these features may be noted in some patients with chronic or full-blown forms, such patients are adjusting at a definite psychotic level and present little difficulty in diagnosis.

The proper management and treatment of schizophrenic patients depend on prompt diagnosis. As a rule these patients first come to the attention of general medical officers or specialists other than psychiatrists. Unless the diagnosis is suspected, the wide variety of symptoms that these patients present is extremely confusing. They are often misdiagnosed as having organic illnesses, psychoneuroses, or character disorders ("psychopathic personalities"), or are simply dismissed as malingerers.

ANXIETY

One of the most significant and least often recognized indications of schizophrenia is the presence of intense and prolonged anxiety. Both the subjective and objective aspects of anxiety are usually thought to be associated with the psychoneuroses. To many medical officers, complaints of "nervousness" or clinical signs of anxiety automatically signify that the patient is a "neurotic." Actually the neuroses, by their very nature, are defenses against anxiety, and severe anxiety is seldom present in the neuroses for a period of more than a few hours or days. On the other hand, it is often present in early or insidious schizo-

From Army Medical Service School, Brooke Army Medical Center, Fort Sam Houston, Tex. Dr. Burkett is now at Veterans Administration Hospital, Sepulveda, Calif.

phrenia. The schizophrenic patient will demonstrate objective evidence of such anxiety: striking tremulousness, widely dilated pupils, flushing, and severe hyperhidrosis. Occasionally widely dilated pupils will be the first clue that a psychotic and not a neurotic condition is present.

Mild or chronic signs and symptoms of anxiety, however, are frequently present in the psychoneuroses, in which anxiety differs qualitatively as well as quantitatively from that in the psychoses. The psychoneurotic patient describes his anxiety as an unknown dread or an *incomprehensible but definitely uncomfortable feeling*. He is unable to explain why he has such unpleasant sensations and he tells of his resultant feelings of helplessness and exasperation. He will stress that his feelings are "silly" and defy logical explanation, and will seldom speak of his feeling of apprehension as one of "fear."

The schizophrenic on the other hand will describe his anxiety in terms of fear. He will *complain of fear of dying, fear that the world is coming to an end, or fear of losing control and killing someone*. The total clinical picture will, of course, necessitate consideration in order to arrive at a correct diagnosis.

Although the psychoneurotic himself is unaware of the cause of his anxiety, a detailed description of his present illness and past history will suggest probable dynamic mechanisms and defense patterns. This is illustrated by the case of a very capable but somewhat overly conscientious sergeant who developed a mild anxiety state for several days after having become a warrant officer. From his history it was learned that he had long-standing dependency needs and conflicts concerning responsibility. These were incompatible with his assumption of a position of greater responsibility. The connection between his anxiety and acceptance of a warrant was quite clear, but the patient himself was not aware of the relationship. *Contrary to this, the schizophrenic's anxiety will bear little relation to his current life situation*. He merely recites his symptoms over and over and no psychodynamic mechanisms are suggested. The somatic components of his anxiety will often be described in a bizarre and inexact manner. In addition, he usually relates many intense feelings, such as great hatred for some member of his immediate family or a multitude of deviant sexual impulses. These are related with little hesitation and accompanied by emotional blandness.

Thus the presence of intense and prolonged anxiety, which shows little relation to current life problems and is described as a *specific fear*, should alert the physician to the possible presence of schizophrenia.

HYPOCHONDRIACAL SYMPTOMS

Hypochondriacal symptoms in a person less than 35 years old almost always turn out to be a symptom of an underlying schizo-

phrenic process. In older patients they may occur as a manifestation of a hypochondriacal neurosis, involutional melancholia, or other psychiatric conditions. The term hypochondriacal symptom is used here in a specific manner and refers to physical symptoms for which no structural or functional disorder is present. Hypochondriacal symptoms are distinguished from symptoms of conversion reactions (hysterical symptoms) and somatization reactions (psychosomatic symptoms). In both of these reactions there is a demonstrable dysfunction. In the former, the individual attempts to defend himself against anxiety by the production of a symptom with a symbolic meaning. In the latter, anxiety is dealt with by being channelized through one portion of the autonomic nervous system and causing dysfunction of an organ or organ system. By contrast, hypochondriacal symptoms bear no relationship to actual bodily dysfunction and are often described in bizarre terms. There are often associated fantastic ideas concerning a supposed physiologic disturbance. In these instances they approach actual somatic delusions. Hypochondriacal symptoms must be distinguished from odd symptoms or descriptions of symptoms which reflect physiologic and anatomic misinformation or ignorance. A patient may, for instance, state: "I have weak kidneys," but actually mean he has a pain in the back which he assumes is related to some kidney ailment.

A physical complaint may not initially appear to be unusual. As the patient elaborates on his symptoms, however, he reveals their peculiar nature. It may require careful questioning and alertness to recognize a symptom's true significance. For instance, an initial complaint of headache may be elaborated by a statement such as "not really a pain but a feeling like the top of my head is going to blow off; the discharge from my nose indicates that the pressure is causing some outflow of brain substance." In one case an initial complaint of numbness in the arms was later found to have a more complex meaning for the patient. He actually felt that there were bubbles of air in the veins of his arms. Furthermore he believed his symptoms were the result of people trying to poison him. Unlike conversion symptoms or psychosomatic symptoms, hypochondriacal symptoms are not influenced by reassurance, placebos, or explanation.

Any hypochondriacal symptom that occurs in a young person, especially if bizarre, necessitates a careful psychiatric evaluation to consider the possibility of an underlying schizophrenic process.

ALCOHOLISM

Severe alcoholic over-indulgence in a young person should alert the medical officer to the possibility of a schizophrenic process. Occasional use of alcohol in the teens or early 20's is of little significance in itself, but when alcoholic intake is

quent and results in severe intoxication, an early schizophrenic process must be considered. This is especially true when alcohol is consumed for the purpose of decreasing overt anxiety or marked feelings of inferiority and inadequacy. It is of less significance when used in an effort to decrease mild social anxiety or an effort to prove that one is able to drink and is therefore mature. If a young adult patient gives a history of repeated alcoholic amnesia ("blacking out spells," "pulling a blank"), there is greater likelihood of a severe emotional disorder, which may be a schizophrenic process. Although alcohol allows the schizophrenic to make a temporary adjustment, it further interferes with his reality testing and a definite psychotic picture finally results.

CONVERSION SYMPTOMS

Gross conversion symptoms such as hysterical paralysis of an extremity, hysterical blindness, and epileptoid seizures always suggest the possibility of a schizophrenic process, and when carefully evaluated, the patient with such a symptom is frequently found to be schizophrenic. Unless a patient with a marked conversion symptom falls into one of the following two categories, the author has found it convenient to presume him to be schizophrenic until proved otherwise:*

1. Mentally defective or borderline mentally defective patients: Such patients may develop conversion symptoms when placed in situations with which they are intellectually or emotionally unable to cope.

2. Patients from unique cultural areas: Gross conversion reactions are fairly common in certain culturally backward areas of the United States and are well known in Puerto Rico. The frequency of bizarre epileptoid convulsions among Puerto Rican patients is common enough to have been labeled the "Puerto Rican syndrome" by some psychiatrists.

Many specific instances are known where improper management resulted from failure to recognize the basic schizophrenic process in patients who presented conversion symptoms. The consequent occurrence of acute severe psychotic episodes required electroconvulsive treatment and prolonged closed ward care. In some cases the patient failed to regain even his previous level of adjustment.

PLASTIC SURGERY CANDIDATES

Patients who request facial plastic surgery in the absence of actual or significant disfigurement are frequently schizophrenic. This is especially true of those who seek operations for plastic surgery on the nose. The intense desire they express for such

*This is not intended to imply that there is no diagnostic entity of conversion reaction. It is beyond the scope of this article to discuss conversion reactions per se.

operations is not reduced by careful explanation regarding the indications for plastic surgery and its limitations. Their desire for correction of minor or nonexistent disfigurements are actually early feelings of depersonalization and withdrawal from reality. Plastic surgery may precipitate a full-blown psychotic reaction in early or insidious cases of schizophrenia.

TINNITUS

Occasionally a chief or sole complaint of ringing or buzzing in the ears in the absence of demonstrable organic cause may be the only indication of a schizophrenic process. Such ringing or buzzing in the ears precedes the development of auditory hallucinations and other indications of an overt psychosis. Patients often disclose that the ringing resembles a rumble of voices but that they have been reluctant to report this to the medical officer. If the underlying schizophrenic process is unrecognized, repeated unrewarding special examinations result.

SUMMARY

A few clinical hints have been given for the early recognition of schizophrenia. Teaching experience has shown that the significance of certain symptoms and signs are not universally recognized and are not stressed sufficiently in standard textbooks of psychiatry. None of the symptoms or signs mentioned are in themselves pathognomonic of schizophrenia. They should, however, alert the medical officer to the possibility that he is dealing with a basic or underlying schizophrenic process. All too frequently, patients who have early or insidious forms of schizophrenia are not recognized and are mismanaged. Often the result is repeated needless laboratory work or consultations. Sometimes mismanagement results in severe schizophrenic reactions which require prolonged hospitalization and treatment. Most unfortunate are the acts of violence and the suicides that may occur.

PROJECTIVE SOUND TESTING OF EMOTIONALLY ILL PATIENTS

DENNIE L. BRIGGS, *Lieutenant, MSC, USN*
DAVID C. GAEDE, *Rear Admiral, MC, USN (Ret.)*
HARRY A. WILMER, *Commander, MC, USNR*

OBJECTIVE psychologic studies of sound perception and sound association have been few, compared to the many studies of visual perception. Particularly great emphasis in psychologic testing has centered upon the Rorschach and Thematic Apperception Tests, but what is seen and how something is seen is no more important than what is heard and how something is heard.

In general, two types of sound association experiments have been reported in the literature. Skinner¹ described a verbal sumator, later called the tautophone. This is a device for repeating arbitrary samples of speech obtained by permuting and combining certain elemental speech sounds. The repetition of samples may evoke various associations. This method for studying latent speech and projection was then utilized clinically by Shakow and Rosenzweig.² Stone³ presented an auditory apperception test to elicit responses in story form. Here subjects were instructed to write or tell the story based on the sounds they heard. More recently, Davids and Murray⁴ reviewed the literature and presented their "azzageddi" test, which deals with interpretations of direct statements or projections that the subject culls forth.

A study of sound associations that we pursued during the past five years resulted in the development of a series of 21 carefully selected sounds, each lasting from 20 to 50 seconds. These were recorded on two records, which are available to others for research purposes.* Descriptions of how the sounds were obtained from real life and how they were selected and recorded have been published elsewhere.⁵⁻⁷

This article reports certain features from the responses to these stimuli by Navy and Marine Corps patients from the psychi-

Presented at the annual clinical sessions of the American Medical Association, Boston, Mass., December 1955.

From the U. S. Naval Hospital, Oakland, Calif. Lt. Briggs is now at the U. S. Naval Hospital, Navy 3923, FPO, San Francisco, Calif.

**Inquiries regarding these records should be addressed to: Naval Medical Research Institute, National Naval Medical Center, Bethesda, Md. (Attention Comdr. H. A. Wilmer).*

atric service in this hospital. The sample is a group that was carefully selected, not according to psychiatric diagnosis, but on the basis of a history of recent experiences in which sound played a significant part. By significant sound experiences we mean (1) traumatic events such as explosions, crashes, or gunfire, and personal sound distortions such as hearing defects, *organic or hysterical*; (2) *psychotic sound imagery such as auditory hallucinations* in which the sound quality as well as the content was of importance; and (3) unusual sound training necessitated by such service experience as sonar or listening duties, piloting a jet, or serving on a submarine. Each patient then could be thought of, in a measure, as a "sound casualty."

The technic of testing differed from the customary manner in which a psychologic test is given by a specialist. Instead, the sound stimuli were used much as one would use Sodium Amytal, to stimulate anamnestic recall in order to obtain replies to specific questions relating to sound associations and apperceptions. To this end the testing was conducted by the therapist or the would-be therapist. It is of real value that the therapist himself actually hears the patient's response and notes his voice, attitude, and manner, because the insight into a patient's conflict or personality that is obtained is of immediate practical value in his care. The method is thus a device in the physician's armamentarium that may help him to obtain specific answers. This does not mean that extensive quantitative studies should not be *simultaneously pursued*, as is *indeed being done*, but that the practical usefulness of the method in treating patients need not depend upon such studies.

THE EXPERIMENT

The sample consisted of 31 Navy and Marine Corps officer and enlisted personnel, ranging in age from 17 to 41 years. All were men, and 23 per cent had participated in combat during World War II, the Korean conflict, or both. All were hospitalized for psychiatric problems, including character disorders, neurotic difficulties, and psychotic states. Three patients were deaf in one ear, 12 had been treated with Serpasil (brand of reserpine), two had had deep insulin coma following early schizophrenic episodes, and at least three were experiencing auditory hallucinations during the time they were studied. Three were qualified submariners, one was a jet pilot, and two were senior naval officers.

The experiment consisted of presenting the patient with a series of 21 sounds—some taken from the environment, such as the radio, home, playground, and railroad station, and some selected from sound tracts of movies. The patients were told:

You are going to hear a series of recorded sounds. Some of these will be familiar, some strange. All sounds have

associations—they bring memories, stories, thoughts, or feelings to mind. This is true of music, cries, words, et cetera. Sounds have different meanings to different people. We are interested only in the meaning these sounds have for you. Tell me what your first thought is—what comes to your mind—what the sounds tell you. If you wish you may make up a story

Responses of each patient to each sound were tabulated and analyzed for accuracy of perception, unpleasantness or signs of emotional involvement with particular sounds, the use of sounds to recall personal experiences, and the elicitation of material alien or completely extraneous to the sound stimuli being presented.

Accuracy of Sound Perception. Not only do sounds have associations, but they call forth "sound illusions" or "mishearing" in certain individuals. The illusion is the result of mishearing or misinterpreting real auditory stimuli. Owing to established habits of rapid association or the temporary "set" of the mind, the listener mistakes the actual sound for something different. Total misperceptions of individual sounds ranged from 6 to 13 per cent, the highest being reported on a sound involving an aggressive male and a retaliating female. Here a recorded dialogue between a man and a woman, culminating with the woman declaring, "Well, I wouldn't talk if I were you," was heard variously as "I wouldn't take it if I were you" (by a patient who went on to say that his own wife wouldn't be so quiet in that situation and that he'd rarely say such things to her), as "You certainly had nerve," and as "I wouldn't be ashamed if I were you." Another patient didn't even hear the sentence because he was upset by the preceding material.

In regard to the various sounds involving people, condensations of dialogue occurred, seemingly through selective hearing and the placing together of words that would make the final phrase coincide with the patients' own thinking. Total mishearing of one sound involving a young man calling for help amidst a crowd was observed with three patients, who reported the man as saying, "No." The sound reminded one of these patients of someone thrown to the lions, with people cheering as he was being punished. In relation to sounds involving situations other than people, for instance, the sound of running water with music being played in the background, misperceptions also were noted. One patient interpreted this sound as "still water" and then used this misinterpretation as a springboard for telling about his father's liking for the mountains, his father's desertion, his own guilt at having sided with his mother against his father, and how he felt guilty about this now and consequently had joined the service. Slips of the tongue in reporting the associations also occurred,

as in the following example with the sound just mentioned. A depressed patient whose wife had recently left him, taking their child with her, mentioned he had heard a "sympathy" (symphony), while a patient with claustrophobia heard the sound as "someone in a vase" stirring liquid. When examining the life histories and present difficulties of the patients, their distortions, misperceptions, and slips in interpretations have direct bearing on their individual personalities.

Affective Tone. In analyzing the patients' responses, we were particularly interested in the affective quality of their associations. The protocols were scanned for material explicitly stated by the patient that would reveal his present emotional state. It soon became apparent that unpleasantness or sadness was prevalent in the protocols, and even with such rigidly applied criteria as verbal statements themselves, we found up to 23 per cent of the responses to any one sound eliciting associations of sadness, unhappiness, or depressed states. A somewhat moving sound, produced by a man reciting a sad poem against a background of organ music, elicited associations involving the funeral of a patient's father, an active hallucinatory episode involving an upraised arm about to strike someone, and projections of unhappy themes in radio programs, motion pictures, and church sermons, all with personal reference to sadness. It was found that in general the highest numbers of depressed or sad themes occurred with sounds involving human participation, and were especially apparent in relation to calls for assistance, unhappy states such as crying, and tense states involving arguments and aggressiveness. It is believed that the response to sounds portraying human situations calling for action on the part of the listener revealed the inadequacies for which the patients had had to be hospitalized. Their own ineffectualness in dealing with interpersonal relations was thus mirrored in their associations to the sounds.

Personal Experiences. In many instances the sounds had so much meaning to the patients that direct interpretation was entirely avoided, and the sound became merely a stimulus to recall a personal and sometimes deeply moving past experience. The frequency with which this occurred with each of the 21 sounds ranged from 7 to 26 per cent. As expected, those sounds involving human participation brought forth the greatest number of these experiences. The majority were concerned with early events or those involving the immediate family. A sound of a parent-child conflict stimulated comments such as "My own rebellion against my parents" "Like me disciplining my oldest boy" "Just like myself . . . getting beat up all the time" "We were treated like soldiers in that home Is that what a home is really like?" (This last patient was raised in an orphanage and to him the sound suggested movie and TV themes of family

life in an actual home.) Another patient recalled, "My Dad talking to me for something I done wrong," and another, "Sounded like my little boy—someone's going to whip him." On a sound involving a man and woman alternately crying, one patient recalled, "Like a crying jag I had in Pearl Harbor" Another patient responded with, "Reminds me of myself—the voices," and "Like I was in a funeral home."

The power of sounds to bring forth personal experiences that have direct bearing on the illness of the patient is important diagnostically as well as therapeutically. However, it is not known if the sound perception constitutes material unique to this mode of perception—that is, if anything is revealed through this mode that could not easily be gained through interviews or other projective tests involving visual perception.

Extraneous Material. In some of the associations, there were remarks or meanings that seemed to be completely outside the range of the stimulus. At least one such association occurred with each sound. The greatest number (10 per cent) were related to the sound of the parent-child conflict. They occurred mainly in areas where the patient displayed considerable affect, such as disgust, fright, or sorrow. In one case a patient with a hyperalarm reaction asked, "Have you ever noticed the shadow on your wall made by the fan?" He had associated the shadows with the faces of Lincoln and Washington, which was an almost total rejection of the actual sound stimuli. The patient's own history is not lacking in father-son conflict.

Some of the material was set off by the association itself, as if it awakened other memories of the past. Sometimes the patients went on to give personal opinions and reveal wishes, such as: "The old man deserved to have a couple of his arms broken or shot off," and then went beyond the sound in their associations. When presented with a sound of someone walking, one patient recounted his experiences in Korea while another talked of the crying of small children being kicked around.

Extraneous material, either given as associations or stimulated by the sound, plus the association itself, seemed to be related to misperceptions, and in most instances was directly connected with material in the patient's life history.

CASE REPORTS

Two case studies are presented briefly, to illustrate possible applications of sound associations and their meanings in specific sound situations.

Case 1. A Navy pilot was hospitalized with paralysis of the lower extremities. Although his illness was eventually established as a conversion reaction and confirmed by numerous civilian and military con-

sultants, he could not accept the idea that his difficulty could have any psychologic basis, although it had occurred immediately prior to his squadron being sent to sea. His sound associations and behavior during the sound testing offered confirmatory evidence as to the nature of his difficulties and gave even greater insight into the nature of his thinking. The manner in which he reported his associations, using phrases such as, "It's quite obviously . . ." "No question about that one . . ." "I'm sure that was what it was . . ." et cetera, gave indications of his use of rigid, concrete thinking. His rationalizations and denial of emotion supplied further insight into his illness. Typically he stated, "I have no personal associations to the sounds—they do not apply to me," and "I don't suppose you could say that the people were crying . . ." Qualifying and justifying were too frequent not to have meaning.

Case 2. A young married submariner entered the hospital with a diagnosis of possible epilepsy. He had been in the conning tower of a submarine when an explosion occurred in which several men lost their lives. The patient revealed that he was impressed with the fact that such things could happen, and had conscious fears that an explosion might occur again. He also reported having "accident dreams" following the explosion. His sound associations were replete with specific anxieties concerning space, movement, and threat. The submarine, being the epitome of controlled environmental stress, became a realistic and threatening sound situation.

While submerged, the submariner lives entirely in a compartmentalized sound world, where sound is his only means to gauge reality. Reaction to sound situations (stimuli)—for example, the diving alarm, the surfacing alarm, and sonar pings—are means of expedient communication requiring action more rapid than human verbal means will allow. In an enclosed chamber where there are crowded a fantastic number of instruments and indicators which are the only points of reference to the outside world, a submariner's optimum function requires the epitome of control. In contrast, the aviator lives in a world where visual representations of reality are experienced as well as the sounds of his machine with which he closely identifies himself as he relies on his instruments for his cues to action.

SUMMARY

Sound associations were obtained from 31 Navy and Marine Corps patients, each of whom had had some significant sound experience in his recent life in the military situation. Their responses were analyzed in terms of accuracy of perception, emotional involvement, recall of personal experiences, and elicitation of extraneous material evoked by the sound stimuli. Two cases are presented, illustrating possible applications of projective sound testing.

 THE FUTURE OF MEDICINE

Looking into the future we must admit that healing will no longer be the main task of the physician although still a very important one. Medicine must by necessity become preventive medicine. There is no point in letting people break down and suffer from preventable diseases. There are enough sources of suffering in the world that may not be prevented so easily. The major tasks of medicine will be the maintenance and promotion of health, the prevention of disease, healing when prevention has broken down, and finally the social rehabilitation or reintegration of the former patient into society. The doctor's place will no longer be in his office where he would sit waiting for patients; it will be the factory, the mine, the farm, the ship, wherever people convene for work. His headquarters will be the Health Center. Such a program obviously requires the close cooperation of the physician with educators, physical culturists, social workers, administrators, and statesmen. The relation between medicine and sociology will be a very close one.

THE TECHNIC OF CIRCUMCISION USING LOCAL ANESTHESIA

RICHARD D. AMELAR, *Captain, USAF (MC)*

REDUNDANT prepuce and phimosis produce 26 per cent of all admissions for diseases of the genito-urinary system to Air Force facilities for treatment.¹ The figure for circumcision is not reported concurrently, but it must be presumed that this is the fate of most of the cases in this category. On the basis of these figures it is obvious that several thousand circumcisions are performed annually throughout the military services, and that there is a concomitant high loss of effective manpower. For military expediency, the morbidity involved with the procedure of circumcision, and the attendant period of hospitalization, must be kept to an absolute minimum.

Recently, in a tour of hospitals, I was impressed with the totally unnecessary risks involved in routinely performing a high proportion of circumcisions under spinal or general anesthesia. At these hospitals, the patient is admitted at least one full day prior to circumcision and is kept there for from 5 to 10 days post-operatively, and even longer in the instance of the development of postspinal headaches or aspiration pneumonitis.

It would seem appropriate, then, to describe a simple technic for the performance of circumcision under local anesthesia. The patient can be admitted to the hospital the day of the circumcision and discharged to duty on the following day, with a total loss from duty of only 24 hours. Indeed, several medical officers and medical corpsmen promptly returned to duty following circumcision.

There is nothing original about the technic set forth below. It combines the best parts of several different recommended procedures and has evolved into a reliable procedure with a minimum of technical difficulty. It can be easily performed by any medical officer.

From 6604th U. S. Air Force Hospital, APO 862, New York, N. Y. Dr. Amelar is now at 77 Park Ave., New York 16, N. Y.

CONSIDERATIONS

As a preoperative medication, a barbiturate is used to produce psychic sedation and to minimize the minor systemic reactions to local anesthetics, evidenced by apprehension and psychic irritability, which may infrequently occur. For these reasons, 0.2 gram (3 grains) of Seconal (brand of secobarbital sodium) is given orally one hour prior to circumcision. No other premedication is necessary.

A 1 per cent aqueous solution of Xylocaine (brand of lidocaine hydrochloride) has been found to be the anesthetic agent of choice, but when this is not available, procaine hydrochloride may be used with satisfactory results. Xylocaine has the great advantage of having a faster and more prolonged action than procaine, with twice the potency and fewer side effects. For this procedure, a maximum of 15 to 20 ml of the 1 per cent solution is used, and this dosage is well within the limits of safety. Epinephrine is not added because its vasoconstrictor action may result in a bloodless operation, thereby masking small bleeders and increasing the possibility of hematoma formation.

Circumcision sutures should be of interrupted 0000 plain catgut on a small cutting-edge needle. The catgut is readily absorbed and the sutures fall out easily after the wound has healed. A continuous suture would tend to form a noose about the penis, and in the event of an erection produce painful strangulation. Furthermore, should a continuous suture break prematurely, the entire wound would separate.

The nerve supply of the penis is derived from the pudendal nerves which divide on each side into two main branches, the dorsal and the perineal nerves. The dorsal nerves supply the skin on the dorsolateral aspects of the penis and send terminal filaments to the glans. The perineal nerves subdivide into posterior scrotal and muscular branches. The posterior scrotal nerve may send filaments to the ventral portion of the penis.

METHOD

The area is prepared for circumcision by shaving the hair from the region of the base of the penis, then thorough scrubbing with surgical soap, and rinsing off with sterile water, followed by a 1:1,000 aqueous solution of Zephiran (brand of benzalkonium chloride). Alcoholic solutions of Merthiolate (brand of thimerosal) are not used because these can be highly irritating to the sensitive skin of the scrotum. If the prepuce cannot be retracted to clean the glans, this is done as soon as the glans is exposed by the dorsal slit.

The dorsal nerves are blocked on each side at the lateral aspect of the base of the penis. Using a 23-gage needle, a skin wheal

is raised, and then the needle is inserted perpendicularly through the subcutaneous tissues until a definite sense of tissue resistance is felt. This resistance (Buck's fascia) is just pierced by the needle, and then after aspiration (to be sure that the needle is not within a blood vessel) 4 ml of the 1 per cent Xylocaine solution is injected (fig. 1). This procedure is repeated on the opposite side. The subcutaneous tissues on the dorsal and ventral aspects of the base of the penis are then infiltrated with 3 ml of solution each. The penis is now completely anesthetized and the circumcision may be performed. If procaine is used rather than Xylocaine, it will be necessary to wait approximately from 5 to 10 minutes before the anesthetic takes effect.

Figure 1. Injection of anesthetic beneath Buck's fascia.

A crushing Kelly clamp is applied to the dorsum of the prepuce in the midline and two small hemostats are used for retraction. The clamp is removed and the prepuce is cut along the crushed line, producing an almost bloodless incision. Care must be taken not to injure the glans or urethra (fig. 2). The incision is extended along the inner surface to a point 1 cm from the corona of the glans. A suture is inserted through mucosa and skin at the apex of this incision (fig. 3). The ends of this suture are left long and are clamped for retraction during the rest of the procedure.

Figure 2. Incision on dorsal aspect of prepuce.

Figure 3. Placement of suture at apex of dorsal incision.

If only a dorsal slit is desired rather than a complete circumcision, the operation can be terminated at this point by the insertion of a few interrupted sutures along the skin margins. The prepuce is now rolled back completely and the exposed glans is thoroughly swabbed with the Zephiran solution. Using two small hemostats for retraction, a crushing Kolly clamp is applied to the midline of the ventral surface of the prepuce. The clamp is removed and the prepuce is cut along the crushed line, again stopping the incision at a point 1 cm from the corona of the glans. A second suture is inserted through the skin and mucosa at the apex of the ventral incision. The ends of this suture are also left long and clamped for retraction. Using the two sutures as a guide, and using hemostats to stretch the prepuce, the prepuce is cut off on one side (fig. 4), leaving a 1-cm margin around the corona. The same procedure is repeated on the other side. The glans is retracted by the assistant's finger, using a gauze sponge to prevent it from slipping.

Figure 4. Excision of redundant prepuce between dorsal and ventral incisions.

Small bleeding points are controlled with hemostats and 0000 catgut ties. This step is most important to prevent postoperative hematoma formation. A suture for retraction is now inserted on each side, midway between the dorsal and ventral sutures. This divides the circumference of the incision into four equal quadrants, with a retraction suture at each corner. With the assistant

holding two adjacent retraction sutures, the skin edge and the edge of the mucosa are easily approximated with three evenly spaced interrupted sutures in each quadrant. The underlying subcutaneous layer is not included in the sutures. This ensures mobility in the area of approximation of the edges of the incision. The long ends of the retraction sutures are cut and a layer of gauze impregnated with petroleum jelly is placed over the incision. A bandage is applied fairly tightly to the end of the penis as another precaution against hematoma formation.

POSTOPERATIVE CARE

Postoperatively, the patient may be ambulatory. Codeine sulfate is given orally to control any pain the patient may have in the immediate period following the circumcision, but there is no need for it after the first day. The discomfort occasioned by infrequent erections lasts only a day or two. We have not found it satisfactory to administer estrogens for the control of erections, because these drugs may have an unpredictably long action, which may be more distressing to the patient psychologically than the few erections which cause him discomfort.

The bandage is removed on the first postoperative day and the patient is started on warm soaks four times a day. For this purpose an ordinary drinking glass half filled with warm water is satisfactory. No antibiotics are necessary. All discomfort disappears by the second postoperative day. The soaks are continued until all the sutures fall out, which may take four or five days, but the patient can be back on duty and need not be hospitalized for this.

SUMMARY

The use of spinal or general anesthesia for routine circumcision in adults is condemned as being unnecessary and hazardous. A simple, safe, and most effective technic using local anesthesia is available and is especially suitable for use by the military medical officer. Only 24 hours of hospitalization are required when this technic is used.

DIAMOX IN PREECLAMPSIA

HUMBERT L. RIVA, *Lieutenant Colonel, MC, USA*
WOODROW L. PICKHARDT, *Lieutenant Colonel, MC, USA*
MERRILL M. BECKER, *Major, MC, USA*

A STUDY in the management of preeclampsia was conducted at this hospital throughout 1954 and 1955 to compare the diuretic effectiveness of Diamox (brand of acetazoleamide) to that of ammonium chloride and of bed rest alone. Two hundred and twenty-five patients having mild or moderate preeclampsia with fluid retention were admitted during this period. The diagnosis was based on the criteria set forth by the Committee on Maternal Welfare.¹ Toxemias of pregnancy other than preeclampsia were excluded from the study. The following procedures were prescribed for all patients:

Diagnostic determinations:

Blood chemistry studies to determine blood urea nitrogen, carbon dioxide combining power, albumin/globulin ratio, sedimentation rate, uric acid, and sodium chloride, on admission and repeated on the fifth day.

Complete blood count and hematocrit on admission.

Weight on admission and daily thereafter before breakfast.

Blood pressure and fetal heart tones twice daily.

Complete urinalysis, including determination of acetone and diacetic acid, every other day.

Twenty-four-hour quantitative urinalysis for albumin three times weekly.

Twenty-four-hour urinalysis for sodium daily.

Daily fluid intake and output.

Fundusoscopic examination.

Therapeutic regimen:

Bed rest with bathroom privileges.

Presented at the Regional Meeting of American Academy Obstetrics and Gynecology, Washington, D. C., on 7 April 1956.

From Walter Reed Army Hospital, Washington, D. C.

Diet: 1,000 calories, 200 mg sodium, high protein.

Phenobarbital, 0.03 gram, four times a day.

One multivitamin capsule daily.

Ferrous sulfate, 0.3 gram, three times a day.

Of the 225 patients, 78 were eliminated from the study because they were delivered during the period of management. Sixty of the remaining 147 were given 250 mg of Diamox daily for five days, 42 were given 9 grams of ammonium chloride in divided doses daily for five days, and 45 were placed on bed rest alone for the same length of time.

RESULTS

The mean results of similar data from all patients are shown in table 1. The age, gravida, parity, weight at the beginning of pregnancy, weeks' gestation before edema appeared, weight on admission, and total weight gain were comparable for the three groups of patients.

TABLE 1. Comparison of average weight changes in 147 patients with preeclampsia of pregnancy

Data	Mean results in patients treated with		
	Diamox (60 patients)	NH ₄ Cl (42 patients)	Bed rest (45 patients)
Age	26.63	26.98	26.80
Gravida	2.03	2.17	1.87
Parity	0.89	0.16	0.80
Weight at beginning of pregnancy	140.8	137.9	145.0
Week edema manifest	34.5	36.1	34.4
Weight on admission	167.7	164.1	171.5
Total weight gain	26.9	26.2	26.5
Weight loss after five days of therapy*	9.6	7.8	7.2

* Average

After five days of therapy the average weight loss in those patients treated with Diamox was 9.6 pounds, as compared with an average weight loss of 7.8 pounds in those treated with ammonium chloride and of 7.2 pounds in those who were on bed rest alone.

Of the 60 patients treated with Diamox, several had paresthesias and several had blurring of vision caused by ciliary spasm.

These symptoms were transitory. There was one case of hematuria, thought to be the result of the sulfonamide-like structure of Diamox,²⁻¹¹ inasmuch as the patient was known to be sensitive to sulfonamide and had had a similar toxic manifestation.

DISCUSSION

In view of the comparability of all the figures obtained, with the exception of the weight loss of the 60 patients given Diamox therapy, it seems probable that Diamox has clinical significance as an adjunct in the treatment of preeclampsia. It is a diuretic and acid base regulator of low toxicity. Peripheral and circumoral paresthesias occur in some patients, but are mild and transitory. Drowsiness, mild acidosis, blurring of vision, and fever with rashes such as those observed with sulfonamides sometimes occur.

Diamox is a nonbacteriostatic sulfonamide derivative possessing distinctly different chemical structure¹² and pharmacologic activity than those of the bacteriostatic sulfonamides. It is an enzyme inhibitor, acting specifically on carbonic anhydrase. Its diuretic effect is due to retardation of the reversible hydration of carbon dioxide and dehydration of carbonic acid reaction in the kidney. The result is renal loss of bicarbonate ion, which carries out sodium, water, and potassium; without loss of chloride. Diuresis and alkalization of the urine thus occur. Diamox is completely absorbed from the gastro-intestinal tract and is almost completely excreted unchanged in the urine in 24 hours.^{10,11}

As adjunctive therapy in the elimination of excess fluid in the pregnant patient, a single daily dose of 250 to 500 mg is recommended. Therapy should be continued as long as control of edema is required. When oral therapy is impossible, the drug may be administered intravenously or intramuscularly in the same dosage as indicated in the oral form, but oral therapy should be prescribed as soon as practicable. Intravenous doses of from 750 mg to 1 gram have been used with impunity.

SUMMARY

The effectiveness of Diamox in producing diuresis in patients having preeclampsia with edema was compared to that of ammonium chloride and of bed rest alone. The latter proved to be effective, and ammonium chloride added to bed rest was statistically no more effective. Diamox therapy, however, was about 20 per cent more effective in promoting diuresis than either bed rest alone or bed rest plus ammonium chloride.

PSYCHIATRIC ASPECTS OF THE MENOPAUSE

There is no single psychopathological entity in the menopausal period. The emotional illnesses of this time of life are not directly related to glandular deficiency but, rather, are the result of the individual's reaction to physiological, physical and environmental changes taking place. Significant dynamic factors are fear of the menopause itself, reaction to physical aging and loss of physical attractiveness, psychosexual conflicts, the end of the child-bearing period, the feeling of uselessness when the children are grown, and the death of loved ones. A prophylactic approach is indicated; in particular, a healthy and scientific attitude of the patient toward the menopause, and the development of personality assets and interests for the better use of leisure time.

DIABETES

Case 1.

Summary of Clinical History. A 34-year-old former Marine Corps major was brought to the emergency room of a naval hospital at 0515 hours on 25 June 1952. He was semicomatose on admission and within five minutes was comatose. He had been sent to the hospital by a civilian physician who had sent a note along with him stating that he had seen the patient at 0430 hours on the same day and that he thought that the patient was in diabetic or insulin shock, and recommended an emergency blood sugar. At the time, no further history was obtainable, but subsequently it was learned that he had a history of diabetes extending over a period of three years which was controlled by 20 units of insulin daily. In addition, it was learned that sometime during the previous three years he had spent a month at a Veterans Administration hospital where he was treated for cirrhosis of the liver. Ten transfusions were given him during the period of that hospitalization because of bleeding from his gastro-intestinal tract. He was treated again at a hospital for a period of three days in March 1952. Admission complaints then were weakness, fainting, dyspnea, and ascites. He had had "influenza" for the preceding few days and had taken insulin irregularly. There had been no vomiting or diarrhea. Stools were black but he had been taking some form of iron. The diagnoses on discharge were: (1) diabetes mellitus; (2) Laennec's cirrhosis, liver; and (3) secondary anemia. There was a history of "heavy drinking" for the preceding three years. He had worked

*Rear Adm. O. B. Morrison, Jr., MC, USN, Commanding Officer. From the Pathology Service, Capt. Wilmot F. Pierce, MC, USN, Chief.

**Rear Adm. Robert M. Gillett, Commanding Officer.

as a store manager for a paint company after his discharge from the Marine Corps. The day prior to the last admission, he had complained of general malaise and at approximately 0130 hours on 25 June 1952, when he was getting out of bed to go to the bathroom, had tripped on a waste basket in his bedroom and had fallen. At 0400 hours the doctor was called because the patient seemed semicomatose. The doctor advised, by telephone, that the patient be given a glass of orange juice and that he be called if there was no response. The physician was called again at 0430 hours, and when he arrived, the patient was stuporous and mumbled something about insulin. The doctor noted an "acetone breath."

Physical Examination On admission the patient was pale, and no blood pressure reading or pulse could be obtained. The heart sounds were regular, but weak and rapid. His lungs were clear, skin was dry, and his eyeballs were soft. Ascites and pitting edema of the ankles were evident. The spleen and liver were not definitely felt. There was areflexia. There were ecchymoses over the chest.

Course in Hospital. An emergency blood sugar determination was 204 mg per 100 ml; his urine was negative for sugar, acetone, and diacetic acid. He was given 10 per cent dextrose and water and 50 units of insulin intravenously. The admission note stated that this was started just before the blood was drawn for the blood sugar determination. One ampule of caffeine and sodium benzoate and one ampule of vasoxyl (brand of methoxamine hydrochloride) were given. The latter was repeated once. The patient did not respond to any of the treatment and died at 0645 hours on 25 June 1952, before any other investigative studies could be carried out.

Case 2.

Summary of Clinical History. A retired white naval medical officer, 65 years old, was a patient in a naval hospital two times before his final admission. The first was in February 1948 because of polyuria, polydipsia, dry scaly skin, and pleuritis, all of which had been present for several months. He said that he had been completely well until a year before. However, there was a history of mesenteric thrombosis following bilateral thrombophlebitis which, in turn, had complicated varicose ulcers of both legs in 1940. No other significant past history was elicited. His father had died of carcinoma of the prostate gland. He was obese; his blood pressure 165/90 mm Hg. The liver edge was felt 4 cm below the right costal margin; there was hemosiderosis of both legs, and there was 2-plus edema of both lower extremities. His electrocardiogram was reported to be essentially normal. At that time he was found to have diabetes mellitus which was fairly easily controlled with 15 units of protamine zinc-insulin injection and 10 units of regular insulin plus a restricted diet. After a period

of 25 days he was discharged from the hospital. No liver studies were carried out at the time of that admission.

He was admitted again in February 1949 because of shortness of breath, a full feeling in his abdomen, and polyuria. He had made little if any attempt to control his diabetes during the period between these hospital admissions. His blood pressure was 180/80 mm Hg. There was ascites; the edge of the liver was palpable 3 cm below the right costal margin. Blood sugar was 296 mg per 100 ml; carbon dioxide combining power was 19.6 volumes per cent; sugar, diacetic acid, and acetone were all present in his urine. No difficulty was encountered in controlling his diabetes and he was discharged after 18 days with instructions to continue taking 25 units of regular insulin daily. During this admission, his cephalin-cholesterol flocculation was reported to be 4 plus in 24 hours; thymol turbidity was 2 units.

His last admission was on 29 July 1952, and he was comatose at that time. Members of his family stated that he had lapsed into coma the previous day. They also stated that they had noticed jaundice for the first time about two weeks before, and that the patient had had attacks of abdominal pain throughout the previous year, had eaten poorly for several months, and had used alcohol excessively.

Physical Examination. The patient was deeply jaundiced at the time of this admission. The liver was greatly enlarged, nodular, and hard, and the abdomen was distended with fluid. His blood pressure was 136/80 mm Hg.

Laboratory Studies. Hemogram and blood sugar were normal; blood urea nitrogen was 59.5 mg per 100 ml, and his urine was bile stained. An electrocardiogram showed only a prolonged Q-T interval.

Course in Hospital. An indwelling catheter was placed in the bladder, and he excreted about 500 ml of urine daily. Hydration was maintained with 2,000 ml of fluid daily consisting of 5 per cent dextrose solution, Ringer's solution, and normal saline, together with 20 units of insulin. His blood sugar remained normal. He did not gain consciousness and died at 0255 hours on 4 August 1952.

DISCUSSION

Doctor Critzer:* I am going to try to present these two patients today simultaneously, for they paralleled each other very closely. Both were very lackadaisical diabetics. Their diabetes was of relatively short duration—three years in the first case and four in the second. Both had evidence of fairly severe concomitant liver disease, and both, pre-

*Lt. Ben L. Critzer, MC, USNR, Medical Service.

sumably, were alcoholics, although in the case of the physician, the summary states only that an excessive alcoholic intake occurred in the few months prior to his final admission. It is likely that his alcoholic intake was excessive over a longer period of time.

Both patients had had two previous hospital admissions because of difficulties encountered in diabetic management and, what seems more significant, evidence primarily of liver dysfunction and its complications dominating an otherwise not so severe diabetic picture.

The major was first admitted for treatment of cirrhosis, and at that time multiple transfusions were necessary for massive gastro-intestinal bleeding, presumably from esophageal varices. A departure from diabetic management and an associated respiratory tract infection were the reasons for the second hospitalization. Ascites was found at that time.

The physician's first recorded hospitalization resulted in the initial discovery of his diabetes. Associated findings at that time were not only the usual symptoms and pathology of diabetes, but also hepatomegaly, moderate hypertension, "hemosiderosis" of both legs, and dependent edema. There was a past history of mesenteric thrombosis following thrombophlebitis of leg varicosities and ulceration some 12 years before. I am not quite sure that mesenteric thrombosis and thrombophlebitis of the leg are significant in relation to his diabetes. Perhaps they complicated an attack of pancreatitis.

His next admission, a year later, again was because of neglectful management of his diabetes, and at that time a rather severe state of diabetic acidosis developed. However, just as important at that time was the finding of persistent hepatomegaly; ascites had developed, and liver function studies indicated serious hepatic impairment.

On their terminal admissions both patients were comatose, both having become so only a short time prior to being brought to the hospital. The duration of the major's coma was a matter of only an hour or so. On the day prior to his last admission he had complained of general malaise, and a few hours before admission he fell in his room, became semicomatose, and did not respond after he was given some orange juice as advised by his doctor. When he was admitted, peripheral vascular collapse was evident, and he was dehydrated and deeply comatose. Ten per cent dextrose was started shortly before blood for sugar determination was drawn. The result of that determination was 204 mg per 100 ml. There was no clinical improvement and even though stimulants and vasopressor agents were administered, he died promptly.

This is to be considered a rather sudden and rapid demise even for a careless diabetic. That he had serious liver disease there can be no doubt, and with poor nutritional history and excessive alcoholic intake progression was to be expected. Perhaps there is no deadlier combination than diabetes and embarrassment of liver function. Since the liver figures importantly in carbohydrate metabolism and maintenance of a

constant blood sugar level, cirrhotics are extremely prone to insulin shock. Storage and release of glycogen by the liver require insulin, and in a poorly functioning or fatty liver a deficiency in this function develops since there is no place to put this important sugar. It is not hard to conceive of a rapid infusion of dextrose, even for a minute or two, raising the blood sugar to 200 mg per 100 ml, especially since it could not have had time to become evenly distributed throughout the extracellular fluid. Therefore I think it is most likely that this patient died of insulin shock. Although there was a history of a fall and possible head injury, and areflexia found on admission suggested the possibility of intracranial hemorrhage, it would be hard to distinguish between central nervous system embarrassment by massive hemorrhage and its embarrassment by deprivation of necessary nutrition. Injury to the chest at the time he fell should be considered, for this might have initiated another massive esophageal hemorrhage, but except for the profound shock there is nothing noted that would lend credence to this.

The physician, I feel, presented a different problem on his final admission. He had become jaundiced two weeks prior, and there was massive ascites and evidence of renal failure. In addition, his demise was not nearly so rapid; he remained comatose about one week before death. Insulin shock or diabetic acidosis do not seem to have been involved, for control of his diabetes was apparently maintained, at least according to repeated blood sugar determinations. I believe that the greater part of the evidence points toward cholemia or perhaps the so-called hepatorenal syndrome. The presence of cholemia is difficult to prove clinically, for it has been stated that there are no specific findings, except laboratory findings of hepatic failure, that enable one to distinguish between hepatic coma and any other form of coma. These laboratory evidences do not necessarily show any marked change when a patient passes from a state of moderate hepatic dysfunction to what is known as cholemia. Because jaundice need not be present and neurologic findings are not constant, this is largely a diagnosis of anticipation.

Several things are mentioned in the summary which make one think of a basis for concomitant diabetes and liver failure in this patient. The history of chronic dry, scaly skin and hemosiderosis of both legs are frequent findings in hemochromatosis or bronze diabetes. But usually the diabetes is much more severe and requires more insulin for control than was necessary in this patient. The "hemosiderosis" is probably explained on the basis of incompetence and stasis in the veins of the legs, though hemosiderin deposition in the skin is not necessarily a constant in hemochromatosis. Organ involvement is the paramount manifestation. The development of jaundice and discovery of a very large, nodular, hard liver might suggest hepatic malignancy, which also is not too uncommon in hemosiderosis; the incidence is from 10 to 15 per cent.

I feel that, even though a normal blood sugar was found, the first patient died of hypoglycemia in the presence of diabetes and cirrhosis.

The second patient's final episode, I believe, was cholemia and/or "hepatorenal syndrome" resulting in coma—possibly on the basis of hemochromatosis or hepatic malignancy; but I will just stick to cirrhosis.

Dr. Critzer's diagnoses:

Case 1. Hypoglycemia with presence of diabetes and cirrhosis

Case 2. 1. Cholemia and/or "hepatorenal syndrome" in the presence of cirrhosis
2. Diabetes mellitus

PATHOLOGIC FINDINGS

Doctor Pierce: Clinically, both of these men had diabetes and cirrhosis, and at autopsy both had large, cirrhotic livers. The liver of the first patient weighed 3,160 grams, and of the second, 3,850 grams. The incidence of the combination of diabetes and cirrhosis reported in the recent literature varies considerably—from less than 1 per cent to 24 per cent. Adhering to the concept that diffuse hepatic fibrosis develops as a reaction to the accumulation of some substance within the cytoplasm of the hepatic cells, which results in interference with the intra-lobular circulation and leads to malnutrition and degeneration of the parenchyma,¹ and that this is demonstrated in glycogen disease, adult Gaucher's disease, xanthochromatosis, Niemann-Pick disease, and occasionally in amyloid disease, we would expect the incidence to be high. One of the first experimental observations on diffuse hepatic fibrosis was that it developed in depancreatized dogs. That its development in such dogs can be prevented fairly well by adequate therapy with insulin and diet has been shown.² The descriptions of the livers of diabetics in the pre-insulin days frequently mentioned that they were cirrhotic or fatty. Generally good management of diabetes probably accounts for the present less-frequent occurrence of the combination. This is reflected in the reports in the literature; the highest incidence is reported from hospitals and clinics where good control of diabetics is not possible. Conversely, a damaged liver may cause disturbances of blood sugar levels, including hyperglycemia. Whether or not this type of hyperglycemia can be called diabetes mellitus depends, as pointed out by Spellberg,³ on the definition of diabetes, but when it occurs in patients with diabetes, it may complicate this disease severely. Hypoglycemia as a result of liver damage, on the other hand, may result in apparent improvement in a diabetic. The ease of control of the disease in the two patients discussed today, especially terminally in the second, may well have been due to the concomitant cirrhosis.

In the first patient, bleeding from the gastro-intestinal tract had occurred at least once prior to the last admission to the hospital. Definite esophageal varices were not noted at autopsy, but there was a small, active ulcer on the posterior wall of the duodenum. The role of portal hypertension as a cause of peptic ulcer has been stressed by

Palmer.⁴ From his gastroscopic observations in cirrhosis, he thought that both ischemia, as governed by shunting of arterial blood away from the mucosa, and plethora, incident to portal hypertension, may lead to mucosal hypoxia and the development of erosions. There is no doubt that esophageal varices are the most usual source of bleeding in gastrointestinal tract hemorrhage occurring in cirrhosis of the liver, but peptic ulcers, especially superficial ulcerations, occur in numbers significant enough to indicate that there is a causal relationship, and that the assumption that bleeding in patients with alcoholism is from esophageal varices is dangerous.

The influence of diabetes as a cause of peptic ulcer is less clear. In most clinics, the reported incidence is very low. Palmer, in discussing drugs and gastric mucosal injury, included insulin among the drugs that produce such injury, and he cited work done by Hanke,⁵ who found that high parenteral doses of insulin caused distinct macroscopic and microscopic mucosal alterations in eight of 10 cats. Acute erosions occurred throughout the stomach, especially in the distal portion. The distal esophagus and proximal duodenum were also involved. One reason, of course, for a low incidence of peptic ulcers in diabetics is the fairly frequent finding of achlorhydria, as was found in 32.8 per cent of 399 diabetics studied by Joslin and associates.⁶ This number, at least, can be considered as not being candidates for peptic ulcer. In a study of hypoglycemia in relation to duodenal ulcer, Beck⁷ studied 96 patients to ascertain if there might be a greater incidence of hypoglycemia among patients with roentgenographically proven duodenal ulcer, and therefore with an increase of free hydrochloric acid, than in a control group. There were 47 in the group with duodenal ulcer who had free hydrochloric acid; of this number 51 per cent had hypoglycemia (70 mg per 100 ml or less). Forty-nine patients had no ulcer but had symptoms mimicking ulcer. Forty of these had free hydrochloric acid, nine had achlorhydria; five (12.5 per cent) with free hydrochloric acid had hypoglycemia. None of those with achlorhydria had hypoglycemia. If the hypoglycemia in persons with peptic ulcer is related to disturbed insulin secretion, namely, hyperinsulinism, we might infer that overzealous therapy with insulin or, again, poor regulation of insulin dosage might be important factors in the cause of ulceration of the stomach in diabetes, and especially if cirrhosis of the liver and portal hypertension are also present.

Disturbed gallbladder function was present in both of these men. In the first, there was atresia of the cystic duct with atrophy of the gallbladder, and in the second there was cholecystitis and cholelithiasis. There is a high incidence of diabetes in biliary tract disease due to infection calculosis or functional obstruction.⁸ Either may result in diabetes mellitus, pancreatitis, or in both, or at least in pancreatitis followed by diabetes. The cholecystitis and cholelithiasis probably accounted for the frequent attacks of abdominal pain in the second patient.

The immediate cause of death in the first patient was hemorrhage. However, the bleeding was not from any portion of the gastro-intestinal tract. The ulcer, which has been mentioned, showed no sign of recent bleeding. When this man stumbled and fell, the 10th, 11th, and 12th ribs on the left side were fractured, and the fractured ends lacerated the spleen. That hypoglycemia might have accounted for his stumbling as he attempted to make his way to the bathroom cannot be denied, for as Doctor Critzer has stated, the finding of a normal blood sugar after the patient had arrived at the hospital and dextrose had been started intravenously is no assurance that he did not have hypoglycemia.

In the second patient, as in the first, the complication of alcoholism was undoubtedly a potent factor in the inadequate management of his diabetes. There were no gross ulcerations of his esophagus or stomach, but there were large esophageal varices and multiple petechiae of the gastric mucosa and of the mucosa of the small bowel. In addition to his cholecystitis and cholelithiasis, there was a chronic pancreatitis. In the major's pancreas, there was an apparent decrease in the actual number of islets, and in the islets seen there were varying degrees of degenerative change—hyaline degeneration or active fibrosis.

The gross diagnosis of cirrhosis was confirmed microscopically in the livers of both men. In addition to the scarring, there was some degree of fatty metamorphosis in both (fig. 1). The complicating biliary

Figure 1 (case 2). Section of liver showing fibrosis extending into pseudolobules and fatty metamorphosis.

tract disease in the doctor's liver is evidenced by bile stasis in the canaliculi and by the very marked bile duct hyperplasia (fig. 2). Both

Figure 2 (case 2). Section of liver showing bile plugging of canaliculi.

of these occur in portal cirrhosis, but usually not to this degree. The over-all pattern of changes in this liver are those of portal cirrhosis (fig. 3), and the changes are interpreted as portal cirrhosis with complicating biliary tract disease. The latter occurred late, it would appear, after the portal cirrhosis was well established. Both men had some degree of arteriosclerotic heart disease. The kidneys of both men showed a mild to moderate degree of change due to arteriosclerosis, and in the second patient there also was bile nephrosis. The doctor had grade II to III arteriosclerosis of the cerebral arteries, and an incidental finding of interest was a latent carcinoma in his prostate gland.

Pathologic diagnoses:

Case 1.

1. Traumatic laceration of spleen with exsanguination into peritoneal cavity
2. Fracture, simple, complete, left ribs 10, 11, and 12
3. Cirrhosis, liver (diffuse hepatic fibrosis)
4. Diabetes mellitus, clinical
5. Degenerative changes and/or fibrosis, pancreatic islets
6. Peptic ulcer, duodenum

Case 2.

1. Cirrhosis, liver (diffuse hepatic fibrosis) with generalized icterus
2. Diabetes mellitus, clinical
3. Cholecystitis and cholelithiasis and intrahepatic biliary tract disease
4. Pancreatitis, chronic and minimal, acute
5. Arterial and arteriolar nephrosclerosis and bile nephrosis

Figure 3 (case 2). Section of liver showing dense portal fibrosis and bile duct hyperplasia.

LIMITING DEFECTS OF ARMY INDUCTEES IN PHYSICAL CATEGORIES B AND C

BERNARD D. KARPINOS, *Ph. D.*
GRACE SOUTHER

IT HAS been an established procedure in the Army since 1944 to profile each individual at the time of his physical examination for military service. The primary objective of the profiling has been to evaluate, on the basis of the physical examination findings, the individual's physical capacity from a functional rather than from a diagnostic point of view. This is particularly important with respect to individuals found qualified for military service.

Initially, the profile system was established for the purpose of providing an adequate qualitative distribution of the available qualified manpower between the various armed services—a distribution which was very much unbalanced during World War II and which had placed the Army, particularly the Army Ground Forces, in a very unfavorable position.¹ In addition, however, the profiling system aimed at a second, not less important, function; namely, assessing the individual's ability to perform particular military duties.^{1,2}

The profiling has been accomplished by appraising the individual's functional capacity in terms of the well-known *PULHES* factors, which symbolize the following:

P—Physical capacity or stamina: Organic defects, age, build, strength, stamina, height, weight, agility, energy, muscular co-ordination, and similar factors.

U—Upper extremities: Functional use, strength, range of motion, and general efficiency of hands, arms, shoulder girdle, and spine (cervical, thoracic, and lumbar).

L—Lower extremities: Functional use, strength, range of motion, and general efficiency of feet, legs, pelvic girdle, and lower back (sacral spine).

H—Hearing (including ear defects): Auditory acuity as well as organic defects.

It may be noted from the latter table that eye defects, diseases and defects of bones and organs of movement, and psychiatric disorders were the predominant limiting defects. Inductees with such defects comprised about 75 per cent of all inductees in both categories B and C. Refractive errors and defective vision were the most prevalent diagnoses among the eye defects, while the disease defects of the bones and organs of movement consisted mainly of "flatfoot." The psychiatric disorders were primarily psychoneuroses. In view of the large frequencies of these defects, the standards governing the profiling of these particular defects are given below:

Vision

Grade 2: Meets acceptable standards and his visual acuity will not be less than 20/200 in each eye correctible to 20/40 in each eye, provided the defective vision is not due to active or progressive organic diseases.

Grade 3: Meets acceptable standards with a minimum vision of 20/400 in each eye, correctible to 20/40 in one eye and 20/70 in the second eye, or 20/30 in one eye and 20/100 in the second eye. This classification also includes those individuals with any degree of defective vision in one eye from below 20/400 to no light perception if such defective vision is not due to active or progressive organic disease and if vision in the other eye is not less than 20/100 correctible to 20/20 with glasses.

Flatfoot

Flatfoot, as in the case of other defects of the lower extremities, is to be graded 2 if it does not prevent moderate marching, climbing, et cetera, or prolonged effort. It is to be graded 3 if it causes moderate interference with functions but allows sustained effort for short periods.

Psychiatric Disorders

Grade 2: Mild transient psychoneurotic reaction. Mild character and behavior disorders. Borderline mental deficiency.

Grade 3: Mild chronic psychoneuroses. Moderate transient psychoneurotic reaction. Mental deficiency, mild degree. History of transient psychotic reaction.

Eye defects were most prevalent among white inductees; flatfoot was most prevalent among Negro inductees.

GENERAL PHYSICAL EVALUATION

For the general evaluation of the physical fitness of the inductees it seems important to relate the inductees with the most prevalent limiting defects to all inductees (categories A, B, and C), as done in table 3. This table indicates, for instance, that of

TABLE 3. *Number of inductees per 1,000, by race, with selected limiting defects (grades 2 and 3) (1953-1954)*

Most prevalent limiting defects	Number per 1,000 inductees							
	Grade 2			Grade 3			Grades 2 and 3	
	Total group	White only	Negro only	Total group	White only	Negro only	Total group	Negro only
Eye defects	56	60	23	46	50	19	102	42
Diseases and defects of bones and organs of movement	50	48	61	21	22	16	71	77
Psychiatric disorders	15	16	9	10	11	5	25	14

each 1,000 white inductees, 110 individuals (or 11 per cent) had eye defects (60 had an eye defect graded 2 and 50 had an eye defect graded 3), and that of each 1,000 Negro inductees, 77 individuals (or about 8 per cent) were graded 2 or 3 because of defects of bones and organs of movement, primarily flatfoot. It is worth noting that, although the latter defects were predominant among Negroes, in the total evaluation the proportion of Negro inductees with such defects was not much higher than that of white inductees; that is, 8 per cent among Negro inductees as compared with 7 per cent among white inductees. This is due to the fact that there are relatively fewer Negro than white inductees in categories B and C (table 1).

There were comparatively fewer Negro inductees with eye defects, both on a proportionate basis (table 2), and on an absolute basis (table 3).

The data indicate that about 2.5 per cent of the inductees were diagnosed as having some psychiatric disorder, nondisqualifying under the present psychiatric standards. It should be noted that the psychiatric requirements were lowered after World War II.⁴

There are no comparable diagnostic data, as presented in table 2, for enlistees profiled as physical category B or C. It seems, however, that it would not be unreasonable to assume that their diagnostic distribution is likely to be basically the same as those of inductees, though the enlistees differ from the inductees in their proportional distribution by physical category, as indicated above (table 1). Presumably, the diagnostic distributions given in table 2 may be taken as essentially representative of categories B and C of all accessions—enlistees and inductees.

SUMMARY

Based on the PULHES profiling system established by the Army in 1944, all individuals entering the military service are classified in terms of physical categories A, B, and C. This classification is an evaluation of the individual's physical capacity from a functional rather than a diagnostic point of view. Physical category A represents over-all physical capacity above the average, with no physical or minimal physical defects; category B represents over-all average capacity, involving some mild (nonprogressive) physical defects; category C indicates physical capacity below the average, with moderate (borderline) physical defects. These nondisqualifying defects of categories B and C are referred to as "limiting defects."

Separate distributions by physical categories A, B, and C, covering the 1953-1954 period for inductees and voluntary enlistees, indicate that the enlistees have a more favorable per cent distribution than the inductees; i. e., 81:12:7 for enlistees vs. 74:16:10 for inductees in categories A, B, and C, respectively.

A diagnostic distribution of the limiting defects of the inductees in physical categories B and C, obtained for the 1953-1954 period, indicates that these were predominantly eye defects, with refractive errors and defective vision being the most prevalent diagnoses; diseases of the bones and organs of movement, consisting mainly of flatfoot; and psychiatric disorders, primarily psychoneurosis.

Racial differentials were found in both the distribution by physical category and the diagnostic breakdown of the limiting defects.

No comparable diagnostic distribution was available for enlistees. It may be assumed, however, that their limiting defects would in all probability be distributed by diagnosis in essentially the same manner as those of the inductees.

DIABETES AND ISCHAEMIC HEART DISEASE

"At present more than two-thirds of the deaths among diabetics are caused by atherosclerosis, and in 70% of cases ischaemic heart disease is responsible. Moreover, two out of every five diabetics have clinical or electrocardiographic evidence of coronary ischaemia, and a quarter of these are under 40 years of age. The incidence of severe coronary sclerosis among diabetics coming to necropsy is approximately three times the figure for the general population. The frequency of angina is at first sight surprisingly low, until it is realized that more than half the diabetics who develop angina are dead within a year. Finally, the chances of survival after a myocardial infarct are two to three times worse than in a control group. No less than 60% of diabetics die within sixty days of the acute episode, only 16% are alive at the end of five years, and scarcely one survives longer than ten years."

HELICOPTER MOBILE MEDICAL COMPANIES

In the Fleet Marine Force

JOHN E. WING, *Lieutenant, MC, USNR*
JAMES A. ADDISON, *Commander, MC, USN*

THE Fleet Marine Force (FMF) Medical Service was designed some two decades ago to provide medical support for the amphibious assault, an untested combat concept pioneered by the United States Marine Corps. It received its baptism in the victorious assaults of World War II.

With the detonation of atomic bombs over Hiroshima and Nagasaki and subsequent developments in the family of atomic weapons, the amphibious technic has been the subject of searching re-examination. In the last decade, triphibious assault or vertical envelopment, as a countertactic, has become pre-eminent. It is based on the capability of the transport helicopter to provide tactical mobility, surprise, and dispersion.¹

To perform the medical mission in triphibious assault, the First Medical Battalion of the First Marine Division instituted experiments in 1955 to revise thinking and planning for future medical support. This revision was necessary after envisioning combat teams with helicopter mobility which would operate over widely dispersed areas and be subject at all times to dissolution into mass casualties. As a facet of this examination, it was decided to test the practicability of mobilization by helicopter of entire medical collecting and clearing companies.

THE FMF COLLECTING AND CLEARING COMPANY

The medical battalion of a Marine division consists of a headquarters and service company, two 100-bed hospital companies, and three collecting and clearing companies. The latter are unique to the FMF Medical Service. They are responsible not only for collecting and sorting casualties from battalion aid stations in the regimental zone of action, but also for performing emergency lifesaving surgery in their 60-bed hospitals.

The table of organization of a collecting and clearing company is shown in figure 1. For conventional amphibious operations,

from First Medical Battalion, First Marine Division, FMF, Camp Pendleton, Calif.

it is staffed by 4 Navy medical officers, 70 hospital corpsmen, and 22 marines. Its basic medical equipment weighs 12,763 pounds, in addition to the 10-day initial resupply block weighing over 3 tons. It is provided with 1 surgical trailer, 3 utility vehicles, 5 field ambulances, and 3 jeep ambulances.

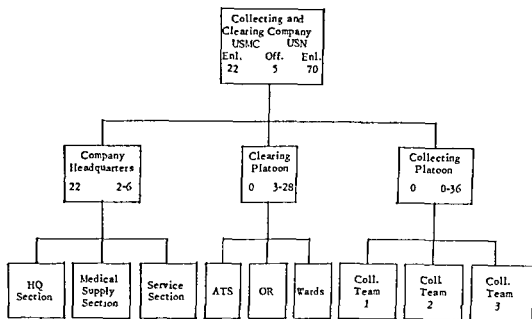

Figure 1. Table of organization of Fleet Marine Force collecting and clearing company.

In the fluid situation of highly mobile triphibious warfare, medical elements operating in support of ground combat teams must possess flexibility of organization, the capacity to incorporate needed additional support elements (shock teams; surgical teams; atomic, biologic, chemical warfare defense and decontamination teams; and preventive medicine teams) and the ability to extrude elements capable of semidetached functioning which may be vitally needed elsewhere. The FMF medical collecting and clearing company is such a unit. Medical elements must also possess the ability to respond smoothly and rapidly with attendant medical equipment to swiftly changing tactical situations. In combat involving the use of atomic weapons by both sides, the ability to airlift on an hour's notice to an area possibly denying entrance by surface vehicle but requiring its services is of the highest import.

THE TRANSPORT HELICOPTER AND DEPLOYMENT OF MEDICAL COMPANIES

At the time of the Korean campaign, when the concept of vertical envelopment was in its inception, the helicopter demonstrated its value in uses ranging from artillery observations to switching entire battalions on the front line, giving evidence from the first

that it represented a major advance in combat. The medical services of both field forces promptly utilized this work horse for evacuation of casualties from the front lines.

Experiments in heli-lifting medical collecting and clearing companies were performed with the admittedly inadequate Sikorsky transport helicopters (HRS) 1 and 3. The limitations imposed on a medical company evolved around the lift capability of this interim transport helicopter, which was from 700 to 1,000 pounds over and above its two-man crew and fuel. Factors such as the temperature of the air, the height above sea level, the level of fuel remaining, the length of flight time, and the condition of the helicopter all entered into any computation of the payload.

Only equipment falling within the lift capability of the HRS as to weight, size, and density could be considered, eliminating all vehicles, 9-kv generators, and shower units. Of the equipment thus eliminated, only the 9-kv generator was critically needed for functioning of the clearing platoon. Substitution of the presently used generators by smaller ones weighing about 250 pounds and capable of providing current for operating-room illumination, suction, and refrigeration would have made it possible to heli-lift the necessary equipment.

Flexible lift priorities for men and equipment were established so that admission, triage, and shock-team equipment and personnel could be functional while other elements were being shuttled in. Equipment loads were prepalletized and arranged so that helicopters could load either internally (fig. 2) or for external lift (fig. 3).

In the first pilot exercise, the assigned medical company minus its 10-day supply block and its vehicles was airlifted by 6 HRS-1 type helicopters provided by Marine Helicopter Transport Squadron 363 (HMR-363), El Toro, Calif., to a site 6 air miles away within 1 hour and 31 minutes from initiation of flight to termination. Forty-five helicopter lifts were required for this particular exercise. Within one hour after the lifting of first priority equipment and personnel, the admission, triage, and shock team was functional. The operating-room team was functional within 2½ hours after the lift commenced; ward teams, within 3 hours; and galley equipment for feeding patients, within 3½ hours.

In a similar exercise in a tactical desert situation at Marine Corps Training Center, 29 Palms, Calif., an entire medical collecting and clearing company complete to its 10-day resupply block but minus its vehicles, was heli-lifted 10 air miles by 6 helicopters of the HRS-3 type (HMR-362) and was functional within 3 hours.

Figure 2. Hospital corpsmen loading field autoclave aboard HRS helicopter.

Figure 3. HRS-3 (H-19) hovering prior to the external lifting of medical equipment of a collecting and clearing company being belifted forward.

The medical company, resupplied by helicopter, is potentially capable of receiving casualties from surface vehicles in the area or brought in by reconnaissance helicopters, and of evacuating via transport helicopters the casualties within its zone of action who require further treatment.

Concomitant with the development of larger helicopters, studies are underway aimed at lightening medical equipment and decreasing the time required for establishing medical functions. The recent report of Storer and Krebs² on the development of radiothulium portable x-ray equipment for use in field hospitals is an example of this effort. The adaptation of the lightweight "Mity-Mite" and "Mule" as ambulances will further increase the potentiality for total heli-lift of medical units (figs. 4 and 5).

Figure 4. Marine HRS helicopter lifting "Mity-Mite." This light-weight vehicle can be converted into an ambulance.

Figure 5. Hospital corpsmen evacuating casualty from front line to battalion aid station in the "Mule," lightweight vehicle.

Figure 6. A 42-foot diameter geodesic dome being transported by two HRS type helicopters. This shelter can, with modifications, serve as triage or operative area.

Evaluation has been made within this battalion of adapting preassembled geodesic domes, which can be lifted by two HRS type helicopters (fig. 6), to use as triage, ward, and surgical areas in place of field tents. Continuing experiment along these lines, to adapt medical organizations to developing helicopter mobility, may result in potentially useful technics.

SUMMARY

A Fleet Marine Force medical collecting and clearing company has been expeditiously moved by the presently used helicopter (HRS). The helicopter is visualized not only as a rapid means of casualty evacuation, but also under certain tactical situations as an essential agent for increasing the mobility of medical units.

THE PROBLEM OF NUCLEAR INDUSTRY

"Radioactive wastes from reactors must be segregated or diluted to tolerable concentrations. At present, underground storage and ocean burial are among the methods used or proposed for segregation. Both the economy and the adequacy of these methods are under continuing investigation in anticipation of the probable increase in volume of radioactive wastes.

"It is estimated that nuclear power plants completed during 1964 alone will have a power level exceeding 2.25×10^6 kilowatts, producing wastes each year of 3.3×10^{10} gallons containing 10 millicuries per gallon. An indication of the magnitude of this activity is that the entire flow of the Mississippi River would not be sufficient to dilute to permissible concentrations the fission products from these plants. Such a method of dilution, of course, is obviously least likely to be used.

the anterior abdominal wall, or air in the region of the right kidney.²

Treatment. Immediate diagnosis and surgical intervention is imperative for such a condition. After attempts at correcting shock and electrolyte deficiency, if present, laparotomy should be performed. Retroperitoneal ruptures can easily be overlooked, even with mobilization of the entire duodenum, and should therefore be searched for. Following closure of a retroperitoneal rupture, retroperitoneal drainage should be afforded.

Supportive postoperative therapy in the form of replacement electrolytes, whole blood transfusions when necessary, and antibiotics will decrease the heretofore high mortality of duodenal rupture.

Mortality. The mortality rate has progressively improved. In 1910, Guibé³ reported a 90 per cent mortality in 134 cases. In 1940, Hinton⁴ reported a 45 per cent mortality in 84 cases. In 1949, Siler² reported a 20 per cent mortality in 25 cases. Since then there have been isolated cases reported with no mortalities. Certainly with prompt diagnosis and immediate reparative surgery, the mortality in this type of injury can be kept to a minimum.

SUMMARY

Traumatic rupture of the duodenum is a fairly uncommon but well-known entity. The case presented is unique in two aspects: (1) It is believed to be the first reported of complete transverse division of the duodenum caused by nonpenetrating trauma; and (2) the patient is believed to be the youngest reported in the literature, to have been treated successfully for traumatic rupture of the duodenum.

The most common site of rupture is in the relatively fixed portions of the duodenum. Signs and symptoms depend on whether the rupture is into the peritoneal cavity or into the retroperitoneal space. If the rupture is intraperitoneal, the signs and symptoms are those of acute peritonitis. A retroperitoneal rupture may produce a less stormy course with varying degrees of pain, fever, and leukocytosis.

Prompt diagnosis, correction of shock and electrolyte imbalance, and early surgical repair of the rupture will decrease the high mortality of this condition.

Pituitary Ependymoma

SARKIS S. SARKISIAN, *Commander, MC, USN*
ARTHUR L. SCHULTZ, *Captain, MC, USN*

EPENDYMOA of the pituitary gland is not generally recognized as a primary lesion and a case is presented below which is considered by us to be a primary ependymoma of the pituitary gland. According to Kernohan and Sayre,¹ intracranial ependymomas are the second most common type of gliomas, occurring on an average between 23 and 24 years of age. In their series, 40 per cent of the ependymal tumors were located supratentorially and 60 per cent infratentorially. Of the latter, 90 per cent occurred in the midline and involved the fourth ventricle or cisterna magna. Antoni² proposed that gliomas of the pituitary can arise as ependymomas from the neurohypophysis and stalk. All tumors in this region, then, are not of primary pituitary gland derivation. In fact, Antoni believed that the preponderance of these tumors are ependymal gliomas. Although, anatomically, ependymal lining cells dip into the infundibulum of the pituitary, as illustrated in figure 1, and can conceivably give rise to an ependymoma, there is a remarkable absence of such cases documented in the literature. The question of how often ependymomas of the pituitary occur can be elucidated to some degree by re-examination of tumors of this area and correlation with other applicable information, such as case history and operative or autopsy findings. An organization such as the Armed Forces Institute of Pathology might have material available for such a study.

CASE REPORT

The patient was a 31-year-old woman who after a normal pregnancy three years earlier had amenorrhea and intermittent lactorrhea. Eight months prior to admission she observed blurred and hazy vision in the left eye associated with photophobia. Two months prior to admission she noted that she was almost blind in the left eye.

The physical examination was negative except for visual field studies which revealed a marked restriction of the visual fields on the left side compatible with the pattern of a bitemporal hemianopsia. The impression was primary optic atrophy due to a chiasmal tumor. Roentgenograms of the skull revealed the pituitary fossa to be enlarged with erosion

of the posterior clinoid processes. These findings were considered to be suggestive of local pressure effect compatible with a pituitary tumor.

Figure 1. Midline hemisection of a brain specimen, with pointer demonstrating ependymal reflection into pituitary stalk.

On craniotomy a tumor mass was found to have compressed the left optic nerve. The tumor—gray-brown in color, soft, and friable—appeared to be arising from the pituitary gland, and much of the mass was removed. At this time, it was considered to be a chromophobe adenoma. The patient made an uneventful recovery with good visual improvement of the left eye.

DISCUSSION

It is evident that, although anatomically likely, ependymomas of the pituitary gland are infrequently documented.¹⁻⁵ In such a case of intracranial neoplasm certain pathophysiologic conditions may be expected due to local mechanical pressure on the optic nerve and pituitary gland. Thus, in the case which is presented above, there are the usual changes associated with hypopituitarism, such as amenorrhea.

The microscopic findings in the tumor (figs. 2 and 3) reveal a characteristic histologic appearance of an ependymoma, consisting of spinal cells with abundant cytoplasm arranged in rosettes and pseudorosettes and radially around vascular channels.

Figure 2. Low-power view of pituitary tumor. ($\times 100$)

Figure 3. High-power view of pituitary tumor, revealing characteristics of an ependymoma. ($\times 240$)

It would appear that not only are pituitary ependymomas to be expected from an anatomic standpoint but that they also exist clinically.

HYPOTENSION FROM RAUWOLFIA DURING ANESTHESIA

*Hypertensive surgical patients on Rauwolfia therapy have shown significant hypotension and bradycardia during anesthesia. . . . This appears to be a vagal response enhanced by the vagotonic anesthetics and corrected by the use of vagal blocking drugs.

*Patients on Rauwolfia therapy who are to undergo elective surgery should not receive this drug for two weeks prior to the surgical procedure. The hazards of removing the antihypertensive and tranquilizing effects of these drugs must be considered before discontinuing therapy prior to a surgical procedure. Emergency surgery on these patients may be safely carried out by using vagal blocking drugs to prevent and treat vagal circulatory responses.

Levarterenol in Cardiac Infarction

With Shock and Transient Complete Heart Block

ARCHIBALD L. RUPRECHT, *Lieutenant, MC, USNR*

INFARCTS of the heart causing A-V dissociation are often fatal. Reported here is a case of total block that lasted a week after infarction; during this period, adequate blood pressure was maintained only with the help of Levophed Bitartrate (brand of levarterenol bitartrate). The patient recovered, however, and even a year later cardiac symptoms were no more severe than prior to the attack. Now that hypotension and slow ventricular rates are more easily treated,^{1,2} the prognosis in such cases may be better, many deaths being from the cumulative effect of several factors. Cardiac output declines as a result of the infarct, but is apt to drop lower with onset of bradycardia so that hypotension is often severe.^{3,4} If fever develops and greater minute output is called for, fixation of rate can be a separate handicap. Ischemia of the myocardium may become so marked as to impair function and favor more dire changes in rhythm.⁵ As the following case suggests, this sequence need not occur regularly, and the often transient nature of the block should emphasize the opportunity for therapy.

CASE REPORT

A 54-year-old white male nurse was admitted to the hospital in May 1954 because of substernal pain of 30 hours' duration, associated with nausea and a single emesis. He had had angina pectoris and mild hypertension for 5 years, with an average blood pressure of 170/90 mm Hg. The only other cardiac symptom was dyspnea on moderate exertion, present for 18 months.

On hospital entry, blood pressure was 128/78 mm Hg; heart rate, 82; respirations, 20; and oral temperature, 97.8°F. No signs of congestive failure were present. The heart was not enlarged to percussion, sounds were of good quality, and the rhythm was regular; a soft systolic murmur was heard just to the right of the manubrium, but the second sound was louder here than at the pulmonic region. Except for mild obesity, there were no other pertinent physical findings.

From Swedish Hospital and the University of Washington School of Medicine, Seattle, Wash. Dr. Ruprecht is now at 750 Belmont North, Seattle 2, Wash.

Examination of the blood revealed a normal value for hemoglobin and a slight leukocytosis, a high percentage of neutrophils being the sole abnormality on smear. The urine was not remarkable. A serum test for syphilis was negative. An electrocardiogram a few hours after entry showed a sinus bradycardia of 50 and changes indicative of a fresh posterolateral infarct with a septal component. The key features were a deep Q wave and S-T segment elevation in lead III; the only notable finding in lead II was a diphasic T wave. In addition, S-T segments were high in leads aVR, aVF, and V₁, but low in leads I, aVL, and V₄ through V₆, the depression being accompanied by T-wave inversion. Position of the heart was intermediate with moderate counterclockwise rotation. P-R and QRS intervals were of normal length, and though all ventricular complexes were slurred, evidence of left ventricular hypertrophy was lacking. A roentgenogram of the chest was not made at this time.

Strict bed rest and oxygen by nasal catheter were provided. Daily doses of phenobarbital were begun and also small doses of morphine as needed to relieve substernal pain. The patient's temperature rose 8 hours after admission to 101.6°F, the start of a marked febrile response that was to last nearly a week. Apart from chest pain and fever, however, the man's course during the first hospital day was uneventful.

The quality of the heart sounds deteriorated by the next morning, and toward midday the pulse rate was regularly around 55. An electrocardiogram at this time showed only typical changes of posterolateral infarction and complete A-V block. The form of the QRS complex was unchanged, indicating a nodal rhythm. The blood pressure began to fall faster and late that afternoon reached 94/60 mm Hg, the patient exhibiting signs of circulatory collapse: anxiety, pallor, and a cold sweat. Fine rales became audible over the lung bases, but other evidence of congestive failure did not develop.

The patient was in this critical state for almost 2 hours before an infusion was started containing 4 mg of Levophed Bitartrate per liter of 5 per cent dextrose in water. Administered at a rate of 20 drops a minute, this restored the patient to preshock status within half an hour. Penicillin was given as prophylaxis, oxygen by tent substituted for the nasal catheter, and in view of a bad prognosis, heparin sodium and Dicumarol (brand of bishydroxycoumarin) were begun.

The rate of flow of Levophed Bitartrate was adjusted to keep blood pressure at about 120/80 mm Hg. A pericardial rub was audible 36 hours after admission and persisted until the next afternoon, the day when some stability in the patient's condition became apparent. Chest pain was milder and less frequent, and in spite of the disposing factors, frank congestive failure was not present. Re-examination of the patient and a second urinalysis failed to disclose an infectious cause for the sustained fever. Penicillin was replaced by a broad-spectrum antibiotic, but the high temperature did not abate.

Late in the third day, the patient complained again of severe substernal pain when the pressor infusion stopped because a clot formed in the needle. There was ashen pallor, and blood pressure was 90/60 mm Hg, changes which proved quickly reversible when Levophed Bitartrate was restarted. This sequence was repeated the next night, and to avoid other similar episodes, a plastic catheter was inserted in an ankle vein. In the process, resumption of this therapy was delayed about two hours, and by then cardiac shock was more advanced. Blood pressure was not recorded lower than 90/60 mm Hg, but the patient was very restless and in a profuse sweat with blotchy cyanosis. Luckily, this deterioration was as easily halted as before.

These bouts of hypotension with each hiatus in therapy are graphed in figure 1. Premature beats were noted at these times, but serial electrocardiograms did not reveal extension of the infarct, showing only evolutionary changes and persistent complete block. The atrial rate was always about twice the ventricular rate of near 50, the form of the QRS complex remaining unchanged.

From the sixth day onward, the patient's course was more favorable as blood pressure was sustained with less Levophed Bitartrate, and both fever and chest pain subsided. Oxygen was continued, however, because the patient became slightly cyanotic if out of the tent for more than a few minutes. Further need for pressor infusion was tested now and then by reducing its rate of flow, the result always being a disturbing drop in blood pressure. The importance of this was substantiated on the eighth day when the patient, in a confused state probably due to barbiturate toxicity, pulled out the venous catheter. Though the full picture of shock did not follow, a marked pallor developed and blood pressure fell to the lowest level in three days (fig. 1). Rational behavior slowly returned once phenobarbital was withheld, and additional Levophed Bitartrate corrected the hypotension.

Eighteen hours after this episode, the ventricular rate rose spontaneously to between 80 and 90, this being the return of A-V conduction after a complete block. The P-R interval was prolonged for a time, but the venous circulation was over and Levophed Bitartrate was stopped with difficulty, blood pressure stabilizing at 115/80 mm Hg. A total of 52 mg of Levophed Bitartrate had been given, and despite typical problems with its administration, there was no trouble from vasospasm near the sites of infusion. With improvement in cardiac function, antibiotic and oxygen therapy was also discontinued.

After three weeks, no abnormalities of the heart could be detected on physical examination, and a chest radiograph showed cardiac and aortic shadows of normal size and contour. Ambulation was begun and Dicumarol discontinued.

At the end of four weeks the patient left the hospital to begin a prolonged rest at home. A year later, he reported the return of mild hypertension and persistent angina, but congestive failure had not

Figure 1. Graph of patient's clinical course showing inability to maintain an adequate blood pressure without Levophed Bitartrate during period of complete A-V block.

nor was there a history of peripheral embolus. He was working full time as a hospital nurse and described his physical limitations as very similar to what they were prior to infarction.

Comment. The crucial role of pressor therapy in the recovery of this patient seems clear. Blood pressure fell rapidly after onset of complete block, and only with Levophed Bitartrate was an adequate level maintained until A-V conduction returned a week later. Hypotension was never marked, but surely cardiac shock existed in view of the clinical picture and the previously high blood pressure. Only at times of circulatory collapse was irregularity of the heart noted, but in cases like this, ectopic beats are often numerous or herald a fatal arrhythmia if hypoxia is not relieved.

Despite the prolonged need for adjuvants, disability seemed the same after recovery, suggesting that much of the acute trouble was related to block. At that time the myocardium was ischemic from hypotension and less able to compensate for the infarcted and inert zone. In turn, low blood pressure was due to decreased systolic power and a slow, as well as fixed, ventricular rate. During the high fever, this rate was no greater than on the seventh and eighth days when the temperature was almost normal and less was demanded of the heart (fig. 1). Fixation of rate was thus an extra factor to limit output at a time when the best possible coronary flow was desirable; although impaired by both the old and fresh cardiac lesions, the stroke volume was being heavily relied on to sustain the circulation. In spite of mild congestive failure, better coronary flow as a result of the rise in blood pressure was enough to restore adequate ventricular function and permit recovery. The effect of Levophed Bitartrate in contracting the peripheral vascular bed probably made this easier. In the patient's favor were the anginal history and high location of the pacemaker, but these features do not detract from this example of the help a pressor agent can be at times.

DISCUSSION

A statistical study alone can show if persons like this patient derive unusual benefit from pressor therapy. Though such benefits have been suspected by other authors, their comment has been brief.⁶ This analysis is offered because a large series is hard to collect, yet cases are common enough to make the point of interest. Many articles report the value of Levophed Bitartrate in shock from a cardiac infarct, and the basis for a better prognosis in this material as a whole is granted.⁶ Thus, attention is drawn only to patients in whom shock and A-V dissociation occur together and to the unique features they present.

Infarcts causing total block are often associated with a very low output, cardiac indexes of 1 and less being on record.⁴ Gen-

erally, so small a value is expected only after a massive infarct or when there is diffuse fibrosis before the attack, cases where the prognosis correlates with the muscular deficit. When bradycardia contributes to the low minute output, however, damage need not be so severe and return of quite good cardiac function is possible. Regardless of stroke capacity, the combination of fresh infarct and slow rate is apt to cause a decline in minute output due just to the vicious effect of ischemia on contractile force.⁷ Though pressor therapy alone will not always be as helpful as in this case, these are patients in whom timely preservation of coronary flow can result in striking recovery.

There are other dynamics which should be considered. Diastolic size of the heart may increase with bradycardia, and if there is dilatation initially, fibers can be so stretched that the force of contraction suffers. Also, when hypervolemia exists, the same drop in minute output is a bigger detriment to the circulation than if blood volume is normal, and output can be low indeed when infarction and total block occur together. Further, when atria and ventricles beat out of phase, ventricular blood is now and then ejected past partly open membranous valves back into the venous trunks.⁸ Such features reveal how important good coronary flow is to these persons so that avoidable ischemia will not make systole any less effective. Pressor therapy keeps to a minimum the weakness that stems from prior cardiac lesions, at a time when full systolic power may be sorely needed.

Of great interest are aspects of the change in rhythm itself. Total block may appear at the time of infarction or not for a day or more. As the region of the A-V node is protected from infarction by a rich anastomosis, this arrhythmia is usually attributed to hypoxia of that zone,⁹ any delay being for ischemia or oxygen unsaturation of the blood to reach a critical level. This is perhaps the rule when block follows an anterior infarct, but if the lesion is posterior, as is usual, conducting tissue can also be caught in the necrosis or the reaction it excites. Onset and duration of block possibly vary on that basis. Inflammation is probably just a minor factor, viable muscle about an infarct having a marginal blood supply that accounts for extension. Extension is more likely if ischemia is aggravated by a marked fall in blood pressure, the very picture infarcts with dissociation are apt to present. It is all the more important to avoid extension in these cases lest block be permanent as a result. Prompt use of Levophed Bitartrate may spare some of these persons this lasting handicap or abolish the arrhythmia and simplify recovery; reports of the latter are already in the literature.⁶ With no other group of myocardial infarcts does pressor therapy have this role.

Fixation of ventricular rate is also a problem at times. Complete block is often thought to imply a fixed rate, but Gilchrist's¹⁰

study of A-V dissociation showed true fixation to be unusual. Regardless of cause, he found a rise of four beats per minute with each degree of fever and a wide range of response to exertion, some persons showing an increase of 50 per cent but others none. That even fever may fail to cause acceleration is seen in figure 1. These differences are probably related to location of the pacemaker and to variable nervous factors, but pertinent here is that fixation occurs. If stroke volume is close to capacity and there is inability to increase heart rate, a febrile illness will challenge the circulation.

When there is fever and need for copious systemic perfusion, limited cardiac output can result in hypotension and a drop in coronary flow. How big a problem total block may be even without pyrexia is shown by the hypometabolism to which chronic cases are prone.^{11,12} The febrile response to an infarct is seldom as marked as graphed here, but serious heart disease is often complicated by infection. Whatever the cause, fever combined with a fixed ventricular rate is a grave threat to persons whose stroke capacity is low. In sustaining pressure by a contraction of the vascular bed, Levophed Bitartrate is especially helpful in such patients, this case being an example.

Even with other adjuvants, pressor therapy is unable to meet the circulatory crises sometimes presented, and then an attempt is made to raise ventricular rate. In years past, ephedrine or epinephrine was usually tried, but use of either entails added risk of ventricular fibrillation and better agents are now available. For this purpose, isopropylarterenol hydrochloride (Isuprel Hydrochloride) and sodium lactate are safer and, judging from a variety of reports,^{1,13,14} often very effective. These new agents are helpful too in abolishing ectopic foci when, though blood pressure normal, ventricular speed is so slow as to lead to hypoxic irritability of heart muscle. Quinidine sulfate is unsafe if there is heart block. With bradycardia easier to manage, more chances to treat these cases successfully are likely.

Besides sustaining blood pressure when cardiac output is limited, effective pressor therapy assures the better perfusion of heart muscle that bradycardia makes possible. During systolic blood vessels in the myocardium are compressed, tachycardia leading to heart failure if diastole becomes too brief for the muscle to be nourished.¹⁵ As a rule, this is seen only with quite high rates, but each contraction makes some foci ischemic, those of the endocardium being susceptible to necrosis because the pressure is close to cavity pressure.^{16,17} Also, even moderate tachycardia seems important to avoid if atherosclerosis limits coronary flow or a fresh thrombus blocks a major conduit.¹⁸ If aortic pressure is low, a slow ventricular rate may allow unusually long diastole, which may be turned to advantage.

showing coronary flow to rise as heart rate falls and greater increments to occur as speeds approach those typical of A-V dissociation.¹⁹ Support is found too in the recent report that angina often disappears with the advent of complete block.²⁰

Only a study of many cases can test such concepts and show if these patients derive special benefit from pressor therapy. Notable, however, is a paper by Binder and associates⁴ on Levophed Bitartrate in shock after cardiac infarction, the most striking results being in a small group with total block. The poor outlook for these persons is usually blamed on the diffuse coronary atherosclerosis often present,⁹ but emphasis on this alone is arbitrary as there seems to be no clinicopathologic review of a large series. As these cases are uncommon, it is hoped this analysis will lead to pooling of experience and more awareness of what therapy offers the occasional patient.

SUMMARY

Infarcts of the heart that lead to complete A-V block are often fatal, yet the high mortality is in part related to the change in rhythm which may be temporary. If coronary flow were sustained during this crucial phase, more of these persons might survive and regain their cardiac function. Vasopressor therapy probably has special value in this situation, as illustrated by the case reported herein. As safe agents are available for raising ventricular rate, there is added reason to recognize the opportunity for treatment that these patients present.

NOT VITAMINS ALONE

"Many patients in a hospital for chronic diseases had been taking large doses of brewer's yeast over long periods of time—months and years. The utter inadequacy of this therapeutic approach was quickly revealed by a mere glance at the large number of cachectic persons in this group. In other words, vitamins per se, or any other preparation designed to stimulate eating, are totally ineffective without provision of a diet containing sufficient calories. We believe that the treatment for undernutrition is a good diet, not vitamin supplements."

DOCTOR BERRY AND GENERAL OGLE VISIT NEW HOSPITAL

Doctor Frank B. Berry, Assistant Secretary of Defense (Health and Medical), accompanied by Major General Dan C. Ogle, The Surgeon General, Department of the Air Force, visited Brigadier General Edward J. Tracy, the Surgeon, Headquarters Air Materiel Command, USAF, at Wright-Patterson Air Force Base, Ohio, on the occasion of the opening of the new U. S. Air Force Hospital at that base.

The new Air Force area hospital, dedicated at Wright-Patterson on 21 September 1956, has facilities for 300 authorized operating beds, with a potential expansion to 426 beds in an emergency or under mobilization circumstances. Complete medical, surgical, and dental care is furnished to military personnel stationed in the Ohio area. This new modern medical facility is the sixth largest of the Air Force hospitals.

A MESSAGE FROM THE A. M. A.

This past year our monthly "Messages" in this *Journal*, with the exception of the one in the October issue, have been devoted to the varied activities and services offered by the American Medical Association. The first article in the series pointed out that the Association has as its objective the promotion of the science and art of medicine and the betterment of public health. It is a physician's organization existing to serve the physician and the general public.

The major emphasis of the American Medical Association is upon its scientific activities. As the last message of this year, it is most appropriate to discuss the purpose and activities of the Council on Scientific Assembly and the Bureau of Exhibits of the Association.

The Scientific Program at the Annual Meeting of the American Medical Association is the culmination of more than one hundred years' experience in program building. Beginning in 1847, there was a gradual increase in the scope and importance of activities at annual meetings until 1915, when the Council on Scientific Assembly was organized by the House of Delegates to correlate the work of the various sections and to stimulate better programs. Meanwhile, in 1899, the Scientific Exhibit had been organized under a separate committee of the House of Delegates. In 1921, the Board of Trustees took over the Scientific Exhibit and administered it under a committee of three members of the Board. This situation of two program committees competing for the attention of the same audience continued until 1953, when the Council on Scientific Assembly was transferred to the Board of Trustees and combined with the Committee on Scientific Exhibit.

The character of medical meetings has changed markedly even during the last half century. At the meeting of the American Medical Association in Denver in 1898, the year before the Scientific Exhibit was initiated, there were 615 papers listed on the program. These were read by "essayists," few of whom had co-authors. At the last meeting of the Association in Chicago in 1956, with a greatly increased attendance over the 1898 meeting and an increase in the various Sections, the number of "papers" had been reduced to 244, nearly half of which were authored by

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.
—Editor

two to five persons working in collaboration. Other features of the meeting included more than thirty panels and symposiums on various subjects, over three hundred scientific exhibits covering all phases of medicine, four full days of color television, which brought the operating room directly into the meeting hall, and a spectacular group of motion pictures, many of which were explained by the authors as the pictures were shown on the screen. The spoken word is still necessary to convey information, but medical audiences prefer to be talked "with," rather than talked "at," and to look rather than merely to listen.

More than fifty persons are responsible for different portions of the program for the Annual Meeting, including the Section Secretaries, the Section Representatives to the Scientific Exhibit, and chairmen of various special committees for different activities such as the special exhibit on fractures. All of these report to the Council on Scientific Assembly, which acts as a clearing house to eliminate duplications and conflicts and to co-ordinate all activities into a smooth-working whole.

The Clinical Meeting of the American Medical Association, which was started in 1948, is intended to supplement the Annual Meeting by going to cities that cannot accommodate large crowds. Interest has been increasing in the Clinical Meeting, and many physicians find the program more interesting than the Annual Meeting because of the intimate character of the presentations. There is a full schedule of lectures, round tables, panels, scientific exhibits, color television, and motion pictures, but the Sections do not meet. The program is arranged with the co-operation of a local committee in the city where the meeting is held.

The Bureau of Exhibits, established in 1930, prepares and presents exhibits that depict activities of the various departments of the American Medical Association. The work is carried on in co-operation with the different councils, bureaus, and committees. It furthers both graduate medical education and public health education by graphically presenting scientific and health materials.

Medical exhibits for professional audiences are shown at meetings of state and county medical societies and gatherings of other medical groups and scientific organizations such as dentistry, pharmacy, and veterinary medicine.

Health exhibits for the public are presented at state and county fairs and other public gatherings. Receptive audiences are found at health fairs and expositions as well as at the occasional World's Fair. Museums, both the health museum as found in Cleveland or Dallas and the Museum of Science and Industry in Chicago, reach millions of people who are in a receptive mood for health education.

MEDICAL SERVICE OFFICERS DECORATED BY REPUBLIC OF PERU

At ceremonies dedicating the new Naval Medical Center of Peru on 4 July 1956 at Lima, Peru, Captain Harry C. Oard, MC, USN, and Lieutenant Commander Charles R. Wannamacher, MSC, USN, were awarded the Peruvian Naval Cross for Merit in the grade of Knight Commander—distinguished as White.

The citations, signed by Rear Admiral Alfredo Sousa Almandoz, Secretary of the Navy of Peru, stated that Captain Oard "as advisor to the Medical Department has given exceptional service to the Peruvian Navy. In the pursuit of his duties, at first as Chief and later as Surgeon General of the Medical Department of the Peruvian Navy, he has at all times displayed the invaluable attributes of his professional capability, training, and experience, and has worked with particular interest for the good of that department. Likewise, he has contributed by his zeal and devotion to the excellent organization and function of the new Naval Medical Center, of which he is the Commanding Officer He has contributed greatly to the longstanding ties of sincere friendship and loyal cooperation which happily exist between the Navies of the United States of North America and Peru."

Lieutenant Commander Wannamacher was praised in the citation Rear Admiral Almandoz "for the magnificent work which he has performed and continues to perform for the better outfitting of the Peruvian Navy."

Naval Medical Center." His efforts have "contributed decidedly in enabling the Naval Medical Center of Peru to fulfill, with true efficiency, its mission for the good of the Navy and the health of its personnel."

Vice Admiral Roque A. Saldías, Secretary of the Navy of Peru, decorating Captain Harry C. Oard, MC, USN, with the Peruvian Naval Cross for Merit.

Lieutenant Gertrude Oard, NC, USNR, wife of Captain Oard, also was decorated with the Peruvian Naval Cross for Merit in the degree of "Officer"—distinguished as White, for as "instructor and advisor in the Art of Nursing in the Hospital Corps School of the Navy (she) has contributed unusually excellent services to the Peruvian Navy."

Among other distinguished guests present at the dedication ceremonies were Rear Admiral Bartholomew W. Hogan, MC, USN, Surgeon General of the United States Navy; Rear Admiral Charles W. Wilkins, USN, Director of Pan-American Affairs, Naval Missions and Advisory Groups Division, Office of the Chief of Naval Operations; Rear Admiral Milton E. Miles, USN, Commandant of the Third Naval District; and Rear Admiral Clarence L. C. Atkeson, USN, Commandant of the Fifteenth Naval District.

The Peruvian Naval Medical Center was built from the plans that were used for the construction of the U. S. Naval Hospital, Beaufort, S. C.

Lieutenant Commander Charles R. Wannamacher, MSC, USN, receiving the Peruvian Naval Cross for Merit from Vice Admiral Roque A. Saldias.

THE HOSPITAL AND THE DOCTOR

Altruism alone does not prompt a doctor, contemplating establishing a practice, to inquire about the hospital facilities of a community. The hardships and inefficiencies of a house-to-house practice, the long vigil at the bedside of a critically ill patient, and the restrictions that are inevitable through distances and lack of trained personnel have little appeal. It is the district served by a good hospital that attracts the members of our profession.

Monthly Message

This is the second of two messages based upon an address given by President A. Whitney Griswold of Yale on the practical value of a liberal education. To answer the questions propounded in my last message, at any one time between the years 1900 and 1950 there were between 10 and 13 million foreign-born with 15 to 25 million of their children in this country. Most of these came from humble circumstances abroad; lands in which liberal education, liberal arts, and the old medieval curriculum and its modern evolutionary counterpart were thought of as the privilege of the well-to-do rather than the opportunity of the many. In 1920, for example, there were 35 million of these people living in the United States; almost a third of our population. Likewise our own Negro citizens have only begun to come into their own during the last 50 years; in 1920 their population was about 10,400,000, which with the 35 million foreign-born and their children made a total of 45 million who had had relatively little educational experience.

The influence of the frontier had both its stimuli and disadvantages. For example, the self-education of Abraham Lincoln under extraordinarily difficult surroundings in early life is known to all of us. Of necessity he read Gibbons' *Decline and Fall of the Roman Empire*, Shakespeare, The Bible, Bunyon's *Pilgrim's Progress*, and when a Congressman, continued his study and mastered Euclid. This type of education is considered out-of-date and many look upon it with scorn.

The phrase "Liberal Arts" means the arts appropriate to free men. In earlier days these were grammar, rhetoric, logic, music, arithmetic, geometry, and astronomy; all now a part of what we call arts and sciences. Their purpose was not to fill the mind with factual knowledge but to train one to use one's mind in inquiry and exploration. Liberal arts provide a humane conception of a society in which one lives, surrounded by technological devices and practices; it gives the lawyer or doctor historical and philosophical breadth, and supplies enlightenment, taste, virtue, and imagination to all. These values have been damaged by the very school system that has striven to uphold them, false ideas that students are a nuisance and that if it were not for them research would be furthered more than it already is.

Foreword

The *United States Armed Forces Medical Journal* is the medium for disseminating information of administrative and professional interest to all medical personnel of the Department of Defense. The Assistant Secretary of Defense (Health and Medical) and the Surgeons General of the several services invite all medical officers, dental officers, Medical Service Corps officers, Nurse Corps officers, and officers of the Veterinary Corps of the Armed Forces, and the medical consultants of the Army, Navy, and Air Force to submit manuscripts for publication in this *Journal*.

ACUTE CORONARY INSUFFICIENCY

Its Importance in Military Medicine

ARTHUR M. MASTER, M. D.

HARRY L. JAFFE, M. D.

LEONARD E. FIELD, M. D.

ACUTE coronary insufficiency is of interest in military medicine, as in civilian practice, since military life exposes men to situations and conditions capable of inducing coronary insufficiency. This condition arises whenever the coronary circulation becomes inadequate for the needs of the myocardium at the moment. Its occurrence is not limited to older people but also is common in the young. The prevalence of coronary disease is indicated by the mortality statistics. In 1952 it was recorded as causing 325,135 deaths in this country, independent of hypertension and other heart diseases.¹ Thus, it was listed as the cause of more than 60 per cent of all cardiac deaths. As a matter of fact, coronary disease accounts for over 80 per cent of cardiovascular deaths, inasmuch as it is probably the cause of death in the majority of patients with hypertension and in many of those listed as "other myocardial degeneration," "acute myocarditis not specific as rheumatic," et cetera.¹ Postmortem studies indicate that significant coronary disease is present in one out of two apparently healthy men between 36 and 46.² We estimated that over 1,000,000 new attacks of coronary occlusion occur annually in this country.³

These figures hold for all age groups, but it has become increasingly evident that coronary disease, far from being limited to the older age levels, is common in young men. The diagnosis of coronary occlusion is now commonplace in men in their 30's, and it is being detected even in those in their 20's.⁴⁻¹⁶ Enos and his associates¹⁵ found significant narrowing of the coronary

From Mount Sinai Hospital, New York, N. Y. The authors were on active duty during World War II as Capt. A. M. Master (MC) USNR, Lt. Comdr. H. L. Jaffe (MC) USNR, and Maj. L. E. Field, MC, AUS.

Read before the Section on Military Medicine, American Medical Association, Atlantic City, 7 June 1955.

arteries, *i. e.*, 50 per cent to almost complete occlusion, in 15.3 per cent of men killed in action in Korea between the ages of 18 and 48. They reported lesser evidence of gross coronary disease in an additional 62 per cent. Country¹⁴ recently reported 14 cases of acute coronary thrombosis in airmen between the ages of 23 and 35. The most dramatic data demonstrating this fact are obtained in numerous studies during World War II and the Korean episode.⁵⁻¹⁶ In fact, Yater and his associates¹⁴ collected 866 cases in patients under the age of 40.

DEFINITION

There is considerable confusion in the medical literature concerning the meaning of the term coronary insufficiency. Although its effect on the myocardium may be permanent, it usually refers to a transitory and reversible insufficiency of coronary flow. The attack may be induced by obvious conditions or factors capable of inducing coronary insufficiency or may occur spontaneously without an obvious precipitating cause. In the latter case, the attack may at first be indistinguishable from the premonitory phase of coronary occlusion with major infarction.^{17, 18}

Acute coronary insufficiency includes a variegated group of attacks more prolonged and severe than simple anginal episodes, but without the typical signs of major infarction and the characteristic electrocardiographic pattern of coronary occlusion.^{19, 20} In mild attacks of acute coronary insufficiency the electrocardiogram may show no change, but usually RS-T depression and/or T-wave inversion appear (fig. 1). It is transitory in mild cases but persists for several days or weeks in more severe cases. Clinically, no evidence of myocardial necrosis or infarction may appear, or mild fever, leukocytosis, and acceleration of the sedimentation rate may be present, indicating some degree of necrosis. The postmortem material available reveals subendocardial necrosis without acute coronary occlusion.¹⁹ This localization accounts for the type of electrocardiographic change found.

A word is required to define angina pectoris or the anginal syndrome. It is true that each brief episode of pain, almost always precipitated by effort, emotion, or cetera, and quickly relieved by nitroglycerin, represents a transitory state of coronary insufficiency with ischemia. However, we prefer to reserve the term acute coronary insufficiency for more prolonged attacks.

DIFFERENTIAL DIAGNOSIS

In contradistinction to acute coronary insufficiency, acute coronary occlusion, in which there is complete, relatively rapid obstruction of the vessel with through-and-through infarction, presents a characteristic electrocardiographic pattern of RS-T elevation and deep Q waves (fig. 2). The attack occurs spontaneously

Figure 1. A 60-year-old woman developed acute coronary insufficiency 2 days after an operation for carcinoma of the colon. The patient was in shock (blood pressure, 50/20 mm. Hg) at the time tracing A was made. The hemoglobin was 9.5 grams per 100 ml. Mild chest pain was present. The electrocardiogram shows tachycardia with marked RS-T depressions. (B) Same day, following recovery from shock. RS-T depressions now minimal. The patient died 3 days later. Autopsy revealed subendocardial hemorrhages; hemoperitoneum; thrombosis, left hepatic artery.

and may be attended by shock, congestive failure, marked drop in blood pressure, and arrhythmias. The electrocardiogram exhibits permanent changes in 90 per cent of patients.²⁴

There are infrequent exceptions to the criteria just given for differentiating acute coronary occlusion and acute coronary insufficiency and it is not always possible to decide in each case when first seen, into which of these it will prove to fall. Also, the clinical and postmortem findings are not always correlated. For example, acute coronary occlusion occasionally occurs without producing a major infarct; in some instances the course may be very mild and, finally, very rarely only inverted T waves may appear in the usual 12-lead electrocardiogram. Vice versa, in coronary insufficiency, massive, through-and-through infarction on rare occasion occurs without an acute occlusion, at times producing RS-T elevation and/or Q waves in the electrocardiogram. These changes may occasionally be seen briefly in clinical attacks.²⁵

For these reasons, some authors have discarded the term coronary occlusion, grouping acute coronary attacks merely into those *without* and those *with* myocardial necrosis or infarction, regardless of the type of electrocardiogram present or whether acute coronary occlusion is present or not. For the attacks without evidence of infarction, a number of terms have been proposed, *e. g.*, coronary failure,²⁶ slight coronary attacks, acute atypical coronary artery insufficiency,²⁷ and intermediate coronary syndrome. Although all of these designations have some specific validity, it has been our experience that the terminology outlined above has proved to be practical and of clinical value. Acute coronary occlusion and acute coronary insufficiency can be differentiated electrocardiographically in at least 90 per cent of cases.²⁸ We do not think that it is of value to use the term coronary insufficiency in the widest general sense to include all coronary attacks, as has been suggested. The term coronary insufficiency serves a useful purpose, particularly in those cases of acute coronary insufficiency induced by precipitating factors such as those enumerated later; here a distinct clinical, electrocardiographic entity is presented which lends itself to prophylaxis and treatment. Also, it is useful to separate spontaneous attacks of coronary insufficiency, even when attended by subendocardial necrosis, from coronary occlusion with extensive infarction, because of their usually benign prognosis and, therefore, the lesser need for prolonged or intensive treatment. For example, in acute coronary insufficiency anticoagulant therapy is not required since peripheral emboli do not occur and the period of rest is relatively short.²⁹

We should like to repeat that the use of the term myocardial infarction, regardless of the type of electrocardiogram present,

or whether it is caused by coronary occlusion or insufficiency, appears to be inadequate to describe the different types and degree of infarction. If the term myocardial infarction is used as the primary diagnosis, it should be qualified as myocardial infarction secondary to coronary occlusion or to coronary insufficiency. We have adopted this procedure in respect to acute coronary insufficiency, *e. g.*, we divide the latter into spontaneous coronary insufficiency and coronary insufficiency secondary to effort, emotion, hemorrhage, tachycardia, or other factors. Also, we refer to coronary insufficiency with ischemia or with necrosis.

Figure 2. Acute coronary occlusion, second day. Antero-septal infarction with characteristic changes in lead aVL.

INCIDENCE

It is difficult to make any estimate of the incidence of acute coronary insufficiency because many mild attacks are undetected and many more are diagnosed as coronary thrombosis. Yet sufficient data are available to make it evident that this condition is very common and is the usual cause of sudden death. Thus, Levy and Bruenn²⁸ found no evidence of coronary occlusion in 337 of 376 fatal cases of acute coronary disease, and Kroetz²⁹ reported 45 per cent without coronary occlusion. Hallermann³⁰ found that 79 per cent of sudden deaths in a series of coroner's cases were caused by coronary sclerosis without thrombosis. French and Dock⁸ reported that in 51 of 80 cases of sudden death from coronary disease in young soldiers, there was no evidence of occlusion. Newman³¹ stated that postmortem examination in 39 patients who died of coronary disease revealed 29 to be free of thrombus in the vessels. Moritz and Zamcheck¹¹ found that there was no coronary occlusion in three fourths of 300 cases of sudden death caused by coronary sclerosis in young soldiers.

In another investigation of sudden cardiac deaths Munck¹² found coronary sclerosis without thrombosis in 255 of 396 patients. Poe¹² failed to find evidence of coronary occlusion in five of nine fatal cases of coronary disease in young men. Master, Carroll, and Andrews⁷ found a similar incidence in a naval hospital. In a detailed report of 450 autopsies in men 18 to 39 years of age who died of coronary disease, Yater and his co-workers¹⁴ discovered a thrombotic occlusion in only 229, that is, about 50 per cent. Similar findings were reported by Spain and associates.¹

In the last 1,000 consecutive, office, private cardiac consultations by the senior author of the present article, episodes of acute coronary insufficiency were diagnosed in 91 patients, or almost 16 per cent of the 567 patients with coronary disease (table 1). It is our impression that its actual incidence is considerably higher; this would appear in our figures if home consultations were included.

TABLE 1. *Diagnosis in 1,000 consecutive office cardiac consultations**

<i>Organic</i>	704
Coronary disease, chronic	258
Coronary occlusion, acute	218
Coronary insufficiency, acute	91
Chronic rheumatic cardiac valvular disease	66
Hypertension	32
Chronic cardiac valvular disease (nonrheumatic)	26
Congenital	8
Pericarditis	4
Subacute bacterial endocarditis	1
<i>Functional</i>	296

*These represent the primary diagnoses. The order of preference was (1) coronary occlusion, (2) coronary insufficiency, (3) coronary disease, et cetera. Hypertension was present in 253 additional cases.

It is thus evident that acute coronary insufficiency is a common disease in all age levels.

ETIOLOGY

As stated before, acute coronary insufficiency may be induced by conditions rendering the coronary circulation inadequate for the specific requirements of the myocardium.

The *precipitating* factors may be divided into three groups: (1) those increasing the work of the heart, such as effort, excitement, a large meal, sudden rise in blood pressure, fever, acute infections, gastroenteritis, hyperthyroidism, excessive smoking,

acute abdominal conditions, marked changes in temperature; (2) those decreasing the coronary flow, such as shock, hemorrhage, tachycardia, trauma, pulmonary embolism; (3) those altering the composition of the blood such as anemia, carbon monoxide poisoning, excessive altitude. As a matter of fact, in the majority of patients several of these factors are present.

Table 2 lists the activity at the onset of 200 attacks of acute coronary insufficiency studied. It will be seen that two thirds of the attacks began without known precipitating cause. In the remainder, acute hemorrhage, pulmonary embolism, effort, tachycardia, and surgical procedures were the most common exciting conditions. These figures indicate that acute coronary insufficiency usually occurs spontaneously.

TABLE 2. *Activity at onset of coronary insufficiency
(200 attacks)*

Spontaneous	132	Trauma	1
Hemorrhage	12	Acute cholecystitis	1
Pulmonary embolism	10	Acute pancreatitis	1
Unusual effort	9	Gastroenteritis	1
Tachycardia	7	Hypertensive crisis	1
Surgical procedures	7	Postsympathectomy	1
Meals	6	Carbon monoxide	1
Excitement	4	Tobacco and alcohol	1
Asthma	2	Addisonian crisis	1
Acute heart failure	2		

In their cases, Yater and associates¹⁴ found no correlation between the type of activity at the onset of the acute coronary attack and the type of pathologic change in the coronary arteries.

In military service, trauma, shock, acute hemorrhage, and strenuous exertion are apt to be frequent occurrences. Sudden immersion in cold water may occur in naval personnel, and a sudden lack of oxygen in flyers who bail out at high altitudes or whose pressurized cabin is pierced. Acute coronary insufficiency has been reported to occur following sudden excitement, for example, hearing of a death or a heated argument, and activities such as going through an obstacle course, participating in a battle indoctrination course, rescuing a drowning man, crawling through an infiltration course, drilling, pushing a car, flying, participating in a shakedown cruise on a warship, marching, or using an exercise machine. A combination of a heavy meal, smoking, and drinking not uncommonly brings on coronary insufficiency.

The importance of acute hemorrhage in inducing acute coronary insufficiency has been demonstrated by us.^{33, 34} Acute hemorrhage induced fairly severe coronary insufficiency in 4 of 25 patients who came to autopsy.³⁵ In a group of 103 patients ranging from

18 to 79 years of age, all of whom had had varying degrees of hemorrhage, 57 per cent presented clinical or electrocardiographic evidence of acute coronary insufficiency.¹⁴ Shock, tachycardia, fall in blood pressure, and decrease in blood volume were all important factors in the mechanism involved. Anoxemia due to decreased hemoglobin was also important, although the principal factor seemed to be the rapidity of blood loss. It is noteworthy that of the four patients in whom myocardial changes secondary to coronary insufficiency were found at autopsy, two had normally patent coronary arteries, one showed moderate coronary sclerosis, and one severe coronary disease. Thus, coronary insufficiency with necrosis may occur even in persons with normal hearts. Shock and hemorrhage are to be expected among battle casualties and their prompt treatment serves to prevent irreparable heart damage.

In addition, there are several predisposing conditions which favor the development of acute coronary insufficiency. In their analysis of 25 patients who came to autopsy, Horn and his associates¹⁵ noted that the heart was hypertrophied in 22; 14 had severe coronary disease, 5 moderate coronary arteriosclerosis, 6 mild or no atheromatosis; aortic stenosis was present in 5; mitral stenosis in 1, and syphilitic aortic insufficiency in 1. The presence of these structural lesions impairs the ability of the heart to make adequate compensatory changes and accordingly renders the myocardium more vulnerable to acute coronary insufficiency. Yater and associates found cardiac hypertrophy in 52 per cent of their patients; it was of marked degree in 16 per cent. Certain nonorganic states, such as chronic anemia and hyperthyroidism, also predispose to coronary insufficiency.¹⁶

PATHOLOGY

In mild, transitory acute coronary insufficiency no demonstrable changes are found, for the effect of the ischemia upon the heart muscle is entirely reversible. When the ischemia is prolonged or moderately severe, scattered, isolated areas of necrosis result. These vary in size from microscopic foci to larger, grossly visible confluent areas of disseminated necrosis (fig. 3).

The lesions are typically located in the subendocardium and papillary muscles of the left ventricle, and ultimately go on to healing and fibrosis. In the most severe cases, the entire inner shell of the left ventricle may show macroscopic, widespread confluent necrosis, often referred to as "subendocardial infarction." In very rare instances a through-and-through infarct develops.

DETECTION

From the foregoing, the importance of detecting coronary disease in the military services is obvious, in order to avoid ex-

posure to the rigors and strain of military life, including excessive exertion, combat duty, and flying.

ANTERIOR

RIGHT

LEFT

Figure 3. Diagram illustrating extensive disseminated subendocardial necrosis due to severe acute coronary insufficiency. The entire inner shell of the left ventricle was involved. The heart was hypertrophied (575 grams), and moderate coronary arteriosclerosis and aortic stenosis were present. Acute gastrointestinal hemorrhage precipitated the coronary insufficiency.

There should be a greater awareness of coronary disease in young people so that even minor complaints are not overlooked. If there are complaints referable to the heart, a complete cardiovascular examination, including perhaps the 2-step exercise test, should be instituted. It must be remembered that from 40 to 50 per cent of persons with coronary disease and angina pectoris show no cardiac abnormality on examination and have a negative resting electrocardiogram. Such persons, however, almost always show significant changes in the 2-step exercise test.³⁶ It is doubtful that this will be true in many young men with asymptomatic coronary disease, yet, it would be advisable to perform the test in suspicious cases. It should be remembered that the test is positive in about 10 per cent of persons with normal hearts, particularly in tense, anxious people. Each case should be carefully evaluated.

TREATMENT

If acute coronary insufficiency is secondary to a specific precipitating cause, prompt and strenuous treatment of the latter may be lifesaving.

In *paroxysmal tachycardia*, the acute coronary insufficiency may dominate the clinical picture with precordial pain, shock, and electrocardiographic signs of myocardial ischemia. The institution of measures to abolish the tachycardia, such as carotid sinus pressure, digitalis, quinidine, or vasopressor drugs, is essential. If the tachycardia subsides, the signs and symptoms of coronary insufficiency may disappear abruptly.

In acute infections, particularly pulmonary and gastrointestinal infections, the early administration of the antibiotics may prevent coronary insufficiency.

In shock and hemorrhage, restoration of circulating blood volume, blood pressure, and hemoglobin by intravenous infusion of fluid, plasma, and blood is imperative. We have observed many patients in the coronary age group, and even younger, in whom a sudden, massive gastrointestinal hemorrhage produced severe coronary insufficiency manifested by a clinical state simulating acute coronary occlusion, particularly when the internal hemorrhage was unrecognized. The treatment for hemorrhage is adequate blood transfusion which should be instituted before the myocardium is impaired because, once such a state is reached, intravenous infusion is usually of no avail.³⁷⁻⁴⁰ The value of a daily electrocardiogram lies in the fact that, not only is it an objective sign of coronary insufficiency, but also it reveals RS-T depressions and T-wave inversions which may precede the appearance of clinical evidence of coronary insufficiency. Blood should be administered until bleeding has ceased and pulse rate, blood pressures, hemoglobin determinations, and electrocardiograms have been restored to normal values.

The treatment of angina pectoris which appears during hemorrhage is blood replacement.^{33,34,41} The occurrence of chest pain or the aggravation of pain ordinarily experienced by the patient constitutes an urgent indication for therapy. It is significant that chest pain appeared in 18 of the 103 patients reported and in each instance blood transfusion effected either amelioration or disappearance of this complaint.³⁴ The advisability of repeated transfusions may be questioned in patients with organic heart disease, in view of the possibility of inducing left ventricular failure. Such an eventuality is readily admitted. However, we firmly believe that the occurrence of this complication can be prevented, or its severity minimized, even when frequently repeated transfusions are indicated, by careful and slow administration of blood. Constant and studied clinical supervision is imperative.

In surgical procedures, anoxia secondary to anesthesia should be prevented by an open airway and by adequate oxygen intake. One must avoid "pushing" the anesthesia in patients with heart disease or other predisposing factor of coronary insufficiency.

Sufficient oxygen must always be available and proper ventilation is essential. Cyanosis, even if temporary, should be prevented. The type of anesthesia administered, local or general, is less important than the care used in its administration. Postoperative observation and avoidance of pain are extremely important.

Acute pulmonary insufficiency caused by acute pulmonary infection, bronchial asthma, and emphysema is a common precipitating cause for acute coronary insufficiency. The treatment of the pulmonary insufficiency and cor pulmonale with oxygen, bronchodilators, and antibiotics often causes the coronary insufficiency and electrocardiographic changes to disappear entirely. Particular care in the employment of morphine and oxygen is essential since the former may depress respiration in chronic cor pulmonale and high concentration of oxygen may remove the stimulus to respiration. Oxygen is administered intermittently, the percentage gradually increased, and given best under pressure. Bronchodilators such as vaponefrin (brand of racemic epinephrine hydrochloride) are very helpful, and meticorten (brand of prednisone) seems very promising.

In acute coronary insufficiency, recovery from the attack is often complete. We have found that the future outlook of patients following acute coronary insufficiency is usually excellent; more than four out of five live for many years and are able to work steadily.^{42, 43} Therefore, it is our opinion that many, if not most, men in the military services who sustain an attack of coronary insufficiency may be retained if they are placed in appropriate lines of duty.⁴³ Naturally, each case must be evaluated in the light of the cause of the coronary insufficiency and the residual evidence of myocardial disease. Periodic re-examinations should be made and, on the basis of the results, the type of work may be altered from time to time. The majority of these patients should be able to perform useful and even essential work. If anginal pain, dyspnea, or a serious arrhythmia persists, the man should be discharged.

CONCLUSIONS

Acute coronary insufficiency represents a sudden, transitory inadequacy of the coronary circulation for the requirements of the myocardium. It may occur spontaneously or be induced by factors increasing the work of the heart, decreasing the coronary flow, or altering the composition of the blood. It usually occurs in persons with coronary disease and cardiac enlargement but may occur in normal hearts. Death from acute coronary insufficiency is uncommon except in cases of "sudden death." Ordinarily, the patient survives and the outlook is excellent.

Acute coronary insufficiency results in ischemia or necrosis

of the subendocardial region. Because of this localization, the electrocardiogram presents RS-T depressions and/or T wave inversions, differentiating it from coronary occlusion. In the latter, through-and-through infarction occurs and Q waves and RS-T elevation are present in the electrocardiogram. This differential diagnosis holds in over 90 per cent of cases. The use of the terms coronary insufficiency and coronary occlusion is preferable to the unqualified term myocardial infarction.

Acute coronary insufficiency is probably more common than coronary occlusion. Coronary disease and acute coronary insufficiency are frequent in young men. In order to detect coronary disease, minor complaints referable to the heart should be carefully investigated.

Acute coronary insufficiency is a specific clinical and therapeutic entity, particularly when it is induced. Prompt treatment of the precipitating factor may be lifesaving, *e. g.*, frequent transfusions in hemorrhage. Recovery from acute coronary insufficiency is usually complete and most patients are able to return to work which is not strenuous.

LEADERSHIP AMONG PHYSICIANS

Physicians must be intelligent—medical schools quickly separate the wheat from the chaff. And they must be capable of a broad viewpoint from which to regard man and his ills, both physical and social, for medicine is no longer a matter of treating disease and ignoring the person. Because of this latter quality, physicians are peculiarly fitted for leadership in every walk of life, especially in a time when men are ruled more often by emotions and fears than by logic and concern for their fellows.

If we have let the duties of our profession, the obligations of social and financial success, and the very understandable desire for security blind us to these obligations of leadership in a time when it was never more badly needed, then it behooves us to pause for at least an hour or two and take stock. No other profession has the fine heritage and glorious traditions that ours has.

DETECTION OF AORTIC INSUFFICIENCY IN RECENTLY INDUCTED MILITARY PERSONNEL

WILLIAM D. SCHIERMAN, *Captain, USAF (MC)*

EDWIN D. BAYRD, *Major, USAF (MC)*

THE MURMUR of aortic insufficiency, when of low intensity, is one of the most difficult of all murmurs to hear. Because it is characteristically high-pitched, soft in quality, and heard best in an area where bronchial or bronchovesicular breath sounds are normally heard, it is easily missed on routine examination. The problem is compounded if the person is obese or the examination takes place in a room where a number of persons are present. In downtown examining stations, room noise may also be combined with street noises to make the perception of the soft aortic diastolic murmur difficult indeed.

Recently, in the course of routine ward and clinic duty at this hospital, three cases with findings of aortic insufficiency were observed. In contrast with this, in the past year and a half, there has been no instance of a previously undetected mitral lesion, and only one other disqualifying condition with associated physical findings including heart murmur (coarctation of the aorta) which was missed on induction but detected later. Thus, it appears that the screening of personnel with aortic insufficiency was most difficult. The following cases were reviewed in an attempt to determine whether similar errors could be prevented from occurring in the future.

CASE REPORTS

Case 1. A 17-year-old airman was admitted to the hospital from the stockade for evaluation of a murmur that had been heard by the medical officer who examined him on commitment to confinement. The airman had been in the service for only 7½ months. While in basic training, he had been hospitalized on one occasion for an upper respiratory infection; no mention was made at that time of a heart murmur. The patient denied any symptoms of cardiac disease and no history suggestive of rheumatic fever in the past could be obtained. Additional past history was noncontributory.

The patient was a well-developed, well-nourished but not obese Negro, 5 feet 8 inches in height and 140 pounds in weight. The sig-

From U. S. Air Force Hospital, Scott Air Force Base, Ill. Dr. Schierman is now at 4161 Lindell, St. Louis, Mo.

nificant findings were as follows: Blood pressure was 120/10 mm. Hg. The apex impulse was forceful but the heart was of normal size on physical examination. A loud, rushing diastolic murmur, grade IV (basis of VI), persisting throughout diastole, was present. It was loudest along the left sternal border in the third and fourth interspaces, although it could also be heard well in the second interspace to the right of the sternum, and was transmitted over the whole precordial area. A Corrigan pulse, pistol-shot sounds over the femoral arteries, and pulsations in the suprasternal notch were also observed.

Findings of routine blood cell counts, serologic tests, and urinalysis were within normal limits; the sedimentation rate was 2 mm. per hour. An electrocardiogram showed findings of left ventricular hypertrophy (fig. 1) and by fluoroscopic radiographic examination the left ventricle was noted to be slightly enlarged (fig. 2). Throughout his hospitalization the patient's temperature was within normal limits, and evidence of active rheumatic fever was lacking.

A copy of the findings of his induction physical examination was obtained. No mention was made therein of any cardiac murmur or other abnormality. It was interesting to note that blood pressure had been recorded initially as 120/50 mm. Hg, erased, and changed to 120/60 mm. Hg. It was recommended that this patient be separated from the service.

Comment. It was believed that this was a case of aortic insufficiency of rheumatic origin, although a history of rheumatic fever was lacking. The magnitude of the murmur, electrocardiographic and fluoroscopic evidence of left ventricular hypertrophy, and an initial blood pressure of 120/50 mm. Hg suggest that the lesion was present when the airman entered the service.

Case 2. This 22-year-old airman was referred from another air base for cardiac evaluation because of a murmur. He had a definite history of rheumatic fever when 6 years old and a recurrence when he was 12 years old.

He was rejected for military service in January and August 1951, initially for flat feet, and then for a "heart murmur." Then he volunteered for the Air Force in January 1954 he was rejected because of "high blood pressure." Shortly thereafter, on routine selective service physical examination for induction into the Army, he was found acceptable, and on the basis of this examination he was subsequently accepted for enlistment into the Air Force in February. The past history was otherwise noncontributory.

Significant physical findings were limited to the cardiovascular system. Pulsations were noted in the suprasternal notch. No cardiac enlargement was found on physical examination; however, the apex impulse was forceful. A grade III diastolic murmur characteristic of aortic insufficiency was heard in the second interspace just to the

Case 2. This 22-year-old airman was referred from another air base for cardiac evaluation because of a murmur. He had a definite history of rheumatic fever when 6 years old and a recurrence when he was 12 years old.

He was rejected for military service in January and August 1951, initially for flat feet, and then for a "heart murmur." Then he volunteered for the Air Force in January 1954 he was rejected because of "high blood pressure." Shortly thereafter, on routine selective service physical examination for induction into the Army, he was found acceptable, and on the basis of this examination he was subsequently enlisted for enlistment into the Air Force in February. The past history was otherwise noncontributory.

Significant physical findings were limited to the cardiovascular system. Pulsations were noted in the suprasternal notch. No cardiac enlargement was found on physical examination; however, the apex impulse was forceful. A grade III diastolic murmur characteristic of aortic insufficiency was heard in the second interspace just to the

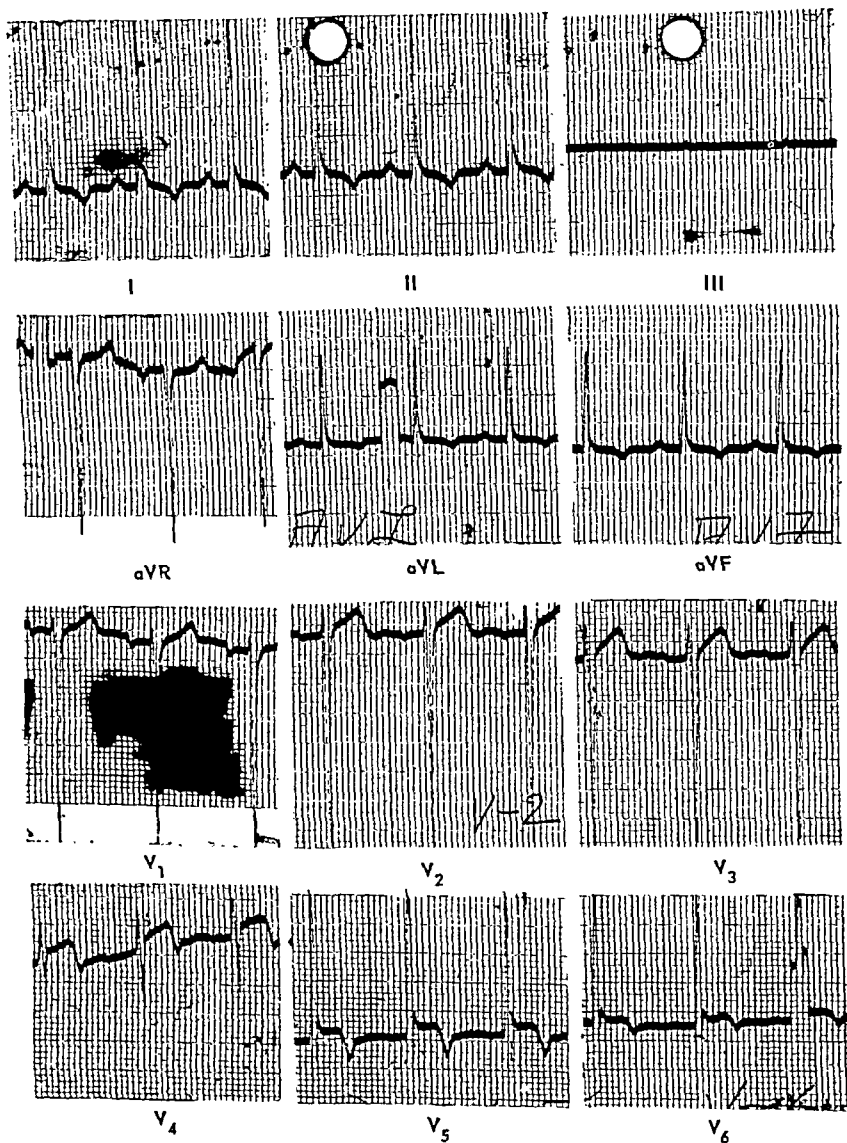

Figure 1 (case 1). Electrocardiogram showing left ventricular hypertrophy. The S wave in V_1 measures 35 mm. The axis deviation index is 32 mm. Upwardly convex S-T segments are present in leads I and II with inverted T waves in leads I, II, V_5 , V_6 , aVL, and aVF. The QRS interval is 0.09 second.

right of the sternum, and in the third interspace just to the left of the sternum. Blood pressures were as follows: right arm, 160/60 mm. Hg; left arm, 170/60 mm. Hg. Pistol-shot sounds were heard over the femoral arteries. The routine blood cell counts, serologic tests, and urinalysis were normal. The sedimentation rate was normal. Postero-anterior and oblique views of the chest showed no roentgenographic

evidence of chamber enlargement. Findings of an electrocardiogram were within normal limits.

Figure 2 (case 1). Roentgenogram of chest showing somewhat boot-shaped configuration of heart.

While in the hospital for evaluation this airman showed no evidence of rheumatic activity. He was examined in consultation with the civilian consultant in cardiology who concurred in the findings, and the patient was then transferred to appear before a physical evaluation board.

Comment. Because of the intensity of this patient's heart murmur and the history of his having been rejected for military service once for a "heart murmur" prior to his acceptable physical examination for the Army, it was believed that a perceptible murmur was present when this man entered the Air Force.

Case 3. A 22-year-old airman was transferred to this hospital for evaluation of a heart murmur detected on examination. He had a definite history of having had rheumatic fever at the age of 6, and he had

been hospitalized in a convalescent home for 1 year. During his convalescence his family was told that he had a heart murmur. He subsequently was followed throughout his childhood and adolescence by a cardiologist, who told him that he would be acceptable for military service. The only suggestion of recurrence of the rheumatic process after the initial attack was at the age of 12 when the patient noticed transient arthralgia for which he was not hospitalized. The patient had enjoyed unrestricted physical activity without difficulty, up to and including the moment when he appeared at the dispensary. He had been in the service for 2 years and was a jet aircraft mechanic. The remainder of the past history was not contributory.

On physical examination significant findings were again limited to the cardiovascular system. A grade II diastolic murmur was heard in the aortic areas as in the previous cases; however, it was necessary to have the patient lean forward in full expiration to hear the murmur clearly. A grade I to II soft systolic murmur was also heard in the mitral area with the patient in the left lateral position. The blood pressure was 125/60 mm. Hg. No pulsations in the suprasternal notch were noted. Faint pistol-shot sounds were heard over the femoral arteries.

On roentgenographic examination the heart presented a globular shape, but no definite chamber enlargement was found by fluoroscopic examination. Routine laboratory data, including serologic tests, were within normal limits and the electrocardiogram was normal.

No evidence of rheumatic activity was observed during the period of hospitalization. Because he had already had 2 years of service and had only a mild degree of aortic insufficiency, this man was returned to duty with a change noted in his physical profile records.

Comment. The history suggests that this airman probably had a murmur at the time he entered service. With the knowledge of previous rheumatic disease more careful examination at that time might have revealed the murmur.

SUMMARY

Three patients with murmurs of aortic insufficiency presumably unrecognized at induction examination demonstrate the difficulty in detecting this condition on routine examination.

Two patients had a history of rheumatic fever, while a third had an abnormally wide pulse pressure recorded at the time of his qualifying examination for military service. It was thought likely that all three patients had had audible murmurs at the time of their initial examination.

Consideration of these cases suggests that prospective inductees with wide pulse pressure, a previous history of rheumatic fever, or other cardiac abnormalities be examined with particular care to exclude the possibility of aortic insufficiency.

EVALUATION OF PSYCHOTHERAPEUTIC SCREENING FOR ENURETIC RECRUITS

RICHARD W. FIRESTONE, *Lieutenant (junior grade) (MSC) USNR*

CARL M. WAGNER, *Lieutenant (junior grade) (MSC) USN*

DANIEL H. HARRIS, *Ph. D.*

THE PROBLEM of nocturnal enuresis among military recruits is longstanding. In a significantly large proportion of cases terminating in general discharge at the recruit level, enuresis plays a very prominent role. Aside from the obvious inconvenience created for the training command, there is also to be considered the matter of expense involved in recruiting and in prematurely discharging the large number of men who at first are assumed to be intractably enuretic.

Investigation into this general area disclosed that several researchers had produced convincing evidence leading to the conclusion that enuresis in adults is primarily psychogenic in origin.¹⁻⁴ With this theoretic assumption as a guide, we suggested⁵ and demonstrated⁷ in earlier reports that the psychiatric screening interview, serving as a brief psychotherapeutic situation, could effectively aid many "borderline" enuretics who in the past might have been discharged as hopeless. Specifically, the screening interview was modified to include a permissive and reassuring discussion designed to relieve anxiety associated with enuresis, together with an attempt to focus positive motivation through plausible behavioral suggestions for overcoming the habit. Experimental results indicated that this procedure was instrumental in reducing by 60 percent the number of potential discharges among enuretics who were so treated, by enabling them to become asymptomatic.

PURPOSE OF THIS STUDY

The therapeutic procedure described above was experimentally verified under necessarily stringent and formalized conditions. Sufficient time having elapsed since the termination of the experimental test period, it now seems appropriate to evaluate the extended effectiveness of this procedure as, less rigidly applied, it has been incorporated into a working routine for the day-to-day screening of enuretic recruits. Whether or not it is practicable, after all, can only be judged under average working conditions which have little in common with the refined control of an experimental atmosphere.

¹From Marine Corps Recruit Depot, San Diego, Calif.

If the hypothesis implied here is valid, then its effect should be reflected in a lower discharge rate for enuretics. In order to evaluate this, all enuretic recruits considered for discharge during equivalent periods before and after the experiment were reviewed, particularly with regard to their final disposition.* The recruits chosen were those in process during the two periods of 41 consecutive weeks preceding and following the experimental test period. Because it is sometimes alleged that enuresis increases in cold weather, both periods included all of the winter months in order to rule out any spurious effect from this source. Data used in this study included the aptitude board decision on each recruit, the General Classification Test (GCT) score, and the psychiatric impression on initial screening (PULHES "S" profile). Equating for general intelligence as measured by the GCT was accomplished by including only persons having scores above 65 (equals Navy GCT of 29). Results of the "S" profile comparisons will be discussed at length below.

RESULTS

A breakdown of the relevant data (table 1) indicates that the aptitude board discharged a substantially smaller number of enuretics in the postexperimental period. On statistical analysis, the 26 percent difference between the pre- and post-experimental groups was shown to be highly significant; *i. e.*, the probability that this result could have occurred by chance alone was negligible. Since the only consistent differentiating factor known to be operating was the therapeutic variable, the results achieved may be attributed to it with a fair degree of certainty. This tends to reaffirm both the soundness and utility of the therapeutic principles developed in our experimental report.

TABLE 1. *Recruits discharged by the aptitude board during pre- and post-experimental periods*

Recruits discharged	Before experiment	After experiment
Total	375	240
Enuretics	229 (61%)*	90 (35%)*

*Chi-square analysis revealed this difference to be significant at better than the .01 level.

To further amplify a comparison of the two groups of recruits, a breakdown was made of the "S" categories to which they were assigned during initial screening. The postexperimental group, as shown in table 2, contained a much higher percentage of psychiatric "suspects," which might suggest that this group was

*Identical criteria for consideration and discharge of such cases were in effect before, during, and after the experiment.

composed of generally poorer material. An alternate supposition could hold that because the "borderline" group of enuretics in the postexperimental group never appeared before an aptitude board due to therapeutic intervention, the 90 discharged persons were the most recalcitrant ones, among whom it could be argued there would be a higher percentage of suspects. While either assumption would lend weight to the implications of the results in table 1, supportive evidence is lacking in both instances.

A better explanation for this discrepancy may lie in the fact that, as a carryover from the experiment, more thorough screening technics were employed with the later group. This could very reasonably have increased the percentage of suspects discovered. The latter possibility also reinforces an hypothesis which the authors voiced in their experimental report with regard to the value of early detection. As in other areas of military psychiatry, the preventive value of early detection is also an important guide in psychiatric screening.

TABLE 2. Percentage of "S" profile categories assigned during pre- and post-experimental periods* (see text)

Category	Before experiment (percent)	After experiment (percent)
S-1	40.8	21.9
S-2 plus S-3 (suspects)	59.2	78.1

*Chi-square based on frequencies for the "S" profile categories was significant beyond the .01 level.

THEORETIC CONSIDERATIONS

If one accepts a psychogenic explanation for adult enuresis, and recent research tends to support such a decision, then it follows that psychotherapy is the treatment of choice. One very recent confirmation is a well-controlled electroencephalographic study on the sleeping levels of enuretics, in which Ditran and Blinn² reached these same conclusions regarding causation and treatment. Closson and Hildreth³ have already demonstrated the usefulness of psychotherapeutic screening in raising the efficiency of recruit training units. With this experimental background, it was not unreasonable to expect that the essential practicability of combining brief psychotherapy for enuretics with initial screening might be strongly indicated.

The effectiveness of this procedure is largely due to the timing and nature of the initial screening interview. Of prime importance is this early opportunity for the new recruit to disclose and re-

ceive help with his problem, motivated as he is toward success and by the stresses he has begun to experience in training. His unique receptivity at this early point in training is a crucial factor. It is believed that the "therapeutic" accepting attitude of the screening interviewer, being one of the first private contacts which the recruit has with an authority figure in a new setting, will tend to have a lasting positive effect.

With most persons the brevity of the interview is apparently no drawback to its effectiveness; nor is a rigid procedure a necessity. As this study demonstrates, significant results were achieved despite a flexible and individual application of therapeutic principles during a very brief period (about 3 minutes). The only attempt at uniformity involved a general acceptance of the necessity for a permissive attitude by the interviewers. Introduced strategically as it was, this resulted in sufficient anxiety reduction to effect a cessation of the habit in many borderline cases of enuresis. The procedural flexibility also had the important advantage of permitting the interviewer to "tailor" the treatment of each case according to his clinical judgment.

The effectiveness, brevity, and flexibility of this approach for handling enuretic recruits speak strongly for its usefulness in the military service. Incorporation into the regular screening routine is possible with little modification beyond emphasizing a psychotherapeutic orientation for the psychiatric staff. The statistics shown in table 1 imply a significant budgetary saving which may be augmented if further research makes it possible to reach beyond the borderline enuretic to effective treatment for less promising cases.

SUMMARY AND CONCLUSIONS

Research to date has tended to establish that psychotherapeutic screening for enuretics is both valid and useful. The following formulation expresses our current thinking as it has evolved from this work.

1. The permissive, interested and accepting attitude of the screening interviewer, a benevolent authority encountered by the recruit at a crucial time in his military training, is the foundation of this technic.
2. The recruit's positive motivation for overcoming the habit may be reinforced by appropriate behavioral suggestions concerning such things as liquid consumption, scheduled nighttime urination, et cetera.
3. Follow-up interviews are desirable in some cases, both to determine progress and to provide additional therapeutic support when necessary.

4. Therapeutic effectiveness is not based on the screening interview alone. The psychotherapeutic orientation of the entire psychiatric unit provides an atmosphere in which this procedure produces the best result.

THE CHANGING PICTURE

In both Europe and America, in industrialized Western European civilization, there is evidence of a striking decline in the gross physical manifestations of hysteria, of the old major hysteria with large loss of motor or sensory functions. The symptoms of hysteria have become more modest, disguised and obscure, and we encounter more frequently hysterical features in many other disorders: anxiety states, character disorders, and such diseases as thyrotoxicosis, essential hypertension, colitis, vomiting in pregnancy, et cetera. There is statistical evidence also that these arbitrarily called psychosomatic disorders are showing a real increase in incidence not accounted for by more frequent diagnosis.

THE RECOGNITION AND MANAGEMENT OF PSYCHIATRIC EMERGENCIES

CHARLES E. HERLIHY, *Lieutenant (MC) USN*

DEAN J. PLAZAK, *Lieutenant (MC) USN*

MANY SITUATIONS that are referable to psychiatric conditions and that require prompt action on the part of medical personnel arise in the setting of a general hospital. It is essential that these emergencies be properly recognized and that the patient be referred for early and necessary psychiatric therapy. This preventive aspect remains a most important goal in the practice of medicine.

SUICIDE

Perhaps the first word that comes to mind when one thinks of a psychiatric emergency is suicide. When a patient succeeds in taking his own life, the feelings of guilt engendered in the staff and family may be very great. There is always embarrassment to the hospital management, not to mention the blow to public relations in the community. Suicide occurs chiefly among the agitated depressed, disturbed psychotic, and delirious patients. At times there is no way of preventing one of these patients from taking his life, because of the swiftness with which he may act. On the other hand there often are clues suggesting that the patient may attempt self-destruction. Generally a patient will commit suicide when going into or coming out of a depression. These are times when psychomotor activity is sufficiently great to allow the patient to expend the energy required to complete the act.

Recognition of early depression is important. The most significant features are a decrease in psychomotor activity, an expression of hopelessness or despair, and talk of suicide. There usually will be a history of a withdrawal of interest from usual activities and an inability to make plans for the future. Loss of appetite and disturbance of sleep are also often prominent in early depression. The patient may have difficulty in falling asleep, but more often he awakes in the early morning hours. If agitated, he may pace the floor. This type of sleep disturbance is a serious sign, because many successful suicides occur in the early morning.

Multiple somatic complaints may be early symptoms of depression. One should get a base line of organic studies, at the same time investigating the life situation of the patient to learn something of his feelings about himself, his goals for the future, and his immediate associations. In the middle-aged patient the complaint of headache may also mask a depression. Management of this type of emergency requires interest in the patient and an attempt to get him to discuss himself instead of his symptoms.

It is well to talk with a member of the family close to the patient regarding his mood and behavior. A problem in the management of the depressed patient is the inherent danger in dispensing barbiturates for sleep disturbances. One must think of the possibility of patients saving barbiturates, remembering that only 10 to 15 times the hypnotic dose of most barbiturates causes death in the average person.¹ It is also important that the physician dispensing barbiturates on an outpatient basis knows fairly reliably how much sleep the patient is getting and what is happening to the medication. Often a member of the family should dispense the medication. It is wise in this respect to advise some member of the family that sleep disturbances frequently are forerunners of depression.

Any attempt at self-destruction must be looked upon with seriousness, because even the gesture of the immature or hysterical patient indicates a serious disturbance in personality and requires thorough evaluation. The suicide gesture usually is seen in the immature, emotionally unstable person or the hysterical personality who may slightly "nick" one or both wrists, take a little bit of iodine or bleach, or swallow three or four sleeping pills. These people hope by such behavior to gain something in their interpersonal relationships.

Once a potentially suicidal patient has been recognized, there are several important considerations in management. He should be placed in a private room with a special watch at all times. The room should be at ground level if possible. There should be a minimum of furnishings: a bed, a chair, and perhaps a night table. One can never be too cautious in removing all articles with which the patient might hurt himself—razor blades, knives, pointed instruments, strings, and ties of any kind. It is wise to avoid the use of drawstring pajamas and to remove shoelaces. The patient should never be left alone.

It is not necessary for the physician to be afraid to discuss suicide with his patient. It is often the physician's own anxiety that prevents this discussion. It may make a difference in management if he evaluates the quality of the attempt through the choice of method. This helps him to decide in the emergency room whether the patient will remain in the hospital or whether

he can be released. It may be more therapeutic and even advisable at times to release the immature person whose gesture has been an attempt to gain affection, love, or understanding. Recognizing some of these features may allow the physician to accomplish this without anxiety.

ACUTE INTOXICATION

Intoxication may exist alone or accompany serious injuries or physical illnesses. The importance of a good physical examination cannot be overstressed. If a good objective history has not helped to identify the intoxicating agent, it is helpful to keep in mind three principal types of drugs: alcohol, bromides, and barbiturates. Routine evaluation of the intoxicated patient should include the examination of blood for all three.

On physical examination, in addition to the frequent appearance of excitement, loss of co-ordinated control, and combativeness, the intoxicated patient usually has injected sclerae and a characteristic breath odor; he also may be incontinent. It is not enough to send this type of person home to "sleep it off." Intoxication represents an acute physical illness and should be so treated. Acute alcoholic death is seen with greater frequency than is generally realized. One often reads in the newspaper of the alcoholic who dies in jail unattended. We show great concern for a child or an adult who has accidentally ingested some other toxicant, but we do not always have the same feeling about the victim of alcoholism. It is not remiss to take the patient to a quiet location, provide him with necessary personal attention, and administer intravenous fluids and vitamins in order to help detoxify him more rapidly.

Barbiturates have been included in the discussion of acute intoxications because of their widespread use and the frequency of acute barbiturate poisoning. It is a great temptation to give barbiturates in order to calm a patient or induce sleep. It is well to remember that in physically ill people smaller dosages are required for a hypnotic effect. In the emotionally ill patient a greater amount of drug may be required, and there is a great temptation to employ large dosages. It is imperative to recall the lethal dosage when dispensing barbiturates regularly to the same patient.¹

An important factor to consider in handling acute barbiturate intoxication is the possibility of the acute withdrawal reaction. Physicians often fail to think of barbiturates as addicting drugs. A patient using large amounts of barbiturates will show a true physiologic reaction on withdrawal of the medication. One must be prepared for this because of the possibility of convulsions and psychotic reactions. If the patient does exhibit a withdrawal

reaction in the form of restlessness, twitching, convulsions, or psychosis, it becomes necessary to reduce the barbiturate dosage gradually, preferably using a different type of barbiturate from the one to which the patient has been addicted.

On physical examination the patient with barbiturate intoxication may show varying degrees of clouding of consciousness, slurred speech, and nystagmus. Reflexes may be normal or hypoactive, and he may not react to noxious stimuli. If the vital signs are stable and remain so over a period of 2 to 6 hours, no other treatment than gastric lavage, maintenance of an adequate airway, and intravenous nutrition is usually necessary. If the patient is in deep coma and vital signs are unstable, intravenous caffeine and sodium benzoate or amphetamine every two hours should be given. It is seldom necessary to use picrotoxin or metrazol (brand of pentylenetetrazol). Intravenous or intragastric feedings may be used. Penicillin given prophylactically is valuable because of the high incidence of pulmonary infections. Recently the use of electrostimulation and of specific chemical antagonists to the barbiturates has been described in the emergency treatment of acute barbiturate overdosage.^{2,3}

Only 25 percent of patients with bromide intoxication have a bromide rash. These patients more frequently show evidence of increased lacrimation and salivation, marked mental aberration with incongruity of thinking, and unusual, bizarre visual hallucinations. The blood bromide level will usually be elevated above 150 mg. per 100 ml.⁴ If possible, it is well in bromidism to use oral medication at first, because too rapid introduction of sodium chloride will cause bromides to go from tissue to blood, thereby elevating the level and causing symptoms to persist. Mercurial diuretics during the first 48 to 72 hours often will aid materially in eliminating the bromide.

Acute amphetamine intoxication is worthy of mention because of the widespread use of this seemingly harmless stimulant. Following excessive use of an inhaler or after ingestion of tablets there may be restlessness, tremors, insomnia, talkativeness, and irritability. In children, confusion, delirium, and hallucinations have been observed. Following excessive oral ingestion, anorexia, nausea, vomiting, and diarrhea may occur; and convulsions, circulatory collapse, coma, and death may follow. Treatment generally consists of gastric lavage and symptomatic care. With marked overdosage, use of luminal sodium (brand of phenobarbital sodium) may occasionally be indicated, but it is cautioned that, in children especially, this may add to the patient's excitement and irritability.

The excessive use of aspirin and antihistamines is frequently of acute intoxication, especially in children; and a vari-

of this type, is interesting as a social problem. This illness frequently becomes a matter of personal concern to the physician, either when it occurs in his own family or in the families of friends and patients who come to him for general advice.

Organic mental syndromes occasionally present a picture calling for emergency measures. These are characterized by excitement, disorientation, and confusion. Simplification of the environment and judicious use of sedatives such as chloral hydrate, paraldehyde, and more recently chlorpromazine hydrochloride constitute the treatment of this syndrome. These disorders frequently produce anxiety in relation to specific occurrences in behavior. Isolated episodes of peculiar behavior, such as a brief flurry of paranoid ideas, an unusual or aberrant sexual act, or confusion in solving a life situational problem, are much more common representations of the beginning of an organic mental syndrome than is a progressive loss of ability to remember, or a deterioration of personal habits.

A careful evaluation of this type of disorder in its incipient stages may be of value in helping those who surround the patient to adjust to the condition, and to assist him in a more orderly adjustment to the continuum of deterioration. The administration of such agents as metrazol in small dosages is of definite value in assisting with this adjustment. Each patient must be evaluated carefully as to need for various types of care. Many times the personal anxiety of the patient's associates over such a syndrome may far outweigh the severity of the disorder itself.

It is important to keep in mind the group of disorders known as the presenile dementias. Such disability, ordinarily expected well after the age of 60, may begin in the fifth or sixth decades; it is more often detected in the military setting because of frequent close physical scrutiny of personnel. Patients with this type of illness require a very thorough neuropsychiatric evaluation.

ACUTE FUNCTIONAL EMOTIONAL DISTURBANCES

Acute emotional disturbances of functional origin are characterized by loss of adequate behavioral or thinking control. This loss may be manifested by an uncontrolled excitement of varying degree or by a severe inhibition. The latter condition includes the acute hysterical conversions. This type of disorder is frequently observed by a physician in a dispensary or emergency room. By its very nature, that of loss of control, it often creates considerable anxiety in the attending staff. It is important that this anxiety does not lead the physician to use hasty and erroneous methods in handling such disorders. One example of this, frequently observed, is the immediate placing of an excited patient in complete restraint before any evaluation is carried out; here is the equally hasty procedure of giving the patient

January 1956)

PSYCHIATRIC EMERGENCIES

sedatives without first determining what is represented by the disorder. The possibility that such an acute excitement may have resulted from either head injury or severe internal injury causing a toxic condition should always be considered.

The best initial approach to a disorder of this type is the use of all perceptive senses. Observe the behavior of the patient. Listen to what he has to say with attention, not so much to the words themselves as to the fashion in which they are spoken and used. A careful evaluation of the symptoms is often helpful in time of onset and quality of the symptoms are often helpful in diagnosis as, for example, in stocking-glove anesthesia or in sudden onset of aphonia or tunnel vision. The quality of the emotional expression, the way in which the story is told, is helpful in that the patient often is not at all concerned over the symptoms that he describes. He does not show the anxiety and feeling about his symptoms that an organically ill patient invariably has.

The second important step is an adequate chronological history. This history is not always obtainable *in toto* from the patient, but there generally is someone, if we take the time to find him, who knows something of the onset of the disorder and has an idea of what the patient's previous difficulty has been. The absence of physical findings to substantiate the complaints presented is an important factor in determining the causes of the disorder.

One should bear in mind that episodes of behavioral excitement, sometimes associated with organic complaints, are extremely common. They often represent transient situational behavior in response to specific stress, which by no means implies a serious continuing mental disturbance. Sometimes one will be able to elicit a history of the previous occurrence of such episodes.

In the treatment of these disorders it is most helpful to show an interest in the patient; to listen to him, watch him, talk with him. As a corollary of this, the physician should avoid becoming anxious or excited in his approach to the problem. If this occurs, it increases the anxiety and excitement of the patient, and reduces his confidence in the physician. An interested and calm approach to the patient will often result in the cessation of his behavior and abrogate the need for further immediate therapy. If it does not, the physician must still, with the same calm approach, consider the use of appropriate sedation or restraints. In this matter, his real professional capacity and ability to handle people reveal themselves to all concerned.

A factor which might contribute to the physician's anxiety in this connection is his own livelihood, which invariably enters

of this type, is interesting as a social problem. This illness frequently becomes a matter of personal concern to the physician, either when it occurs in his own family or in the families of friends and patients who come to him for general advice.

Organic mental syndromes occasionally present a picture calling for emergency measures. These are characterized by excitement, disorientation, and confusion. Simplification of the environment and judicious use of sedatives such as chloral hydrate, paraldehyde, and more recently chlorpromazine hydrochloride constitute the treatment of this syndrome. These disorders frequently produce anxiety in relation to specific occurrences in behavior. sedatives without first determining what is represented by the disorder. The possibility that such an acute excitement may have resulted from either head injury or severe internal injury causing a toxic condition should always be considered.

The best initial approach to a disorder of this type is the use of all perceptive senses. Observe the behavior of the patient. Listen to what he has to say with attention, not so much to the words themselves as to the fashion in which they are spoken and used. A careful evaluation of the symptoms is valuable. The time of onset and quality of the symptoms are often helpful in diagnosis as, for example, in stocking-glove anesthesia or sudden onset of aphonia or tunnel vision. The quality of the emotional expression, the way in which the story is told, is helpful in that the patient often is not at all concerned over the symptoms that he describes. He does not show the anxiety and feeling about his symptoms that an organically ill patient invariably has.

The second important step is an adequate chronological history. This history is not always obtainable *in toto* from the patient, but there generally is someone, if we take the time to find him, who knows something of the onset of the disorder and has an idea of what the patient's previous difficulty has been. The absence of physical findings to substantiate the complaints presented is an important factor in determining the causes of the disorder.

One should bear in mind that episodes of behavioral excitement, sometimes associated with organic complaints, are extremely common. They often represent transient situational behavior in response to specific stress, which by no means implies a serious continuing mental disturbance. Sometimes one will be able to elicit a history of the previous occurrence of such episodes.

In the treatment of these disorders it is most helpful to show an interest in the patient; to listen to him, watch him, talk with him. As a corollary of this, the physician should avoid becoming anxious or excited in his approach to the problem. If this occurs, it increases the anxiety and excitement of the patient, and reduces his confidence in the physician. An interested and calm approach to the patient will often result in the cessation of his behavior and abrogate the need for further immediate therapy. If it does not, the physician must still, with the same calm approach, consider the use of appropriate sedation or restraints. In this matter, his real professional capacity and ability to handle people reveal themselves to all concerned.

A factor which might contribute to the physician's anxiety in this connection is his own livelihood, which invariably enters

into the handling of any patient. In the military setting physicians are, uniquely, not particularly bound by these problems. It is possible to be perfectly frank and honest with the patient in referring him for needed help and in discussing with him the emotional import of his disturbance. This honesty with the patient is often sufficient therapy. He often fully recognizes that his is an emotional difficulty and is only looking for the understanding reassurance of someone who is interested enough to help him through the episode.

Placing a patient with a conversion paralysis in a "straight-jacket" or leather cuff restraints, or even placing a patient with a marked excitement in such a situation without first discussing the matter with him, belies the common-sense approach in dealing with emotional problems. When restraints are necessary, sheets used in the fashion of a wrap-around are often sufficient to assist the patient in overcoming a generalized physical excitement.

Sedation should be used only after obtaining a fairly accurate appraisal of the patient's difficulty. This necessitates discussion of the difficulty with him and an adequate explanation to him of why one is going to use sedation. One of the most effective sedatives is a combination of 1.5 mg. of apomorphine hydrochloride and 0.4 mg. to 0.6 mg. of scopolamine hydrobromide administered by hypodermic injection. The scopolamine may be repeated at intervals of from 3 to 5 hours as necessary. Occasionally this may cause vomiting, but in general one finds that it works well even in acutely disturbed psychotic patients.

The extremely disturbed or violent patient calls for a different approach. One should certainly avoid all semblance of aggressiveness in approaching the patient. It is a well-known fact in mental hospital practice that a firm approach to the patient with appropriate explanation, using a show of adequate personnel and without the use of physical force or restraint of any kind, frequently will quiet the patient because he recognizes the respect for his very disturbed state. Involvement in fights, or aggressive actions and verbalizations toward the patient, indicate only our own fear of inability to deal with the problem.

SUMMARY

Suicide, acute intoxication, delirium, organic mental syndromes, and acute functional emotional disturbances have been discussed with reference to their specific treatment or management in a general hospital.

Successful suicide attempts occur chiefly among the agitated and disturbed psychotic, depressed, and delirious patients. Recognition of early depressive symptoms is an important preventive measure. Suicide gestures are important indicators of underlying emotional disturbance.

January 1956)

PSYCHIATRIC EMERGENCIES

Complications in treatment of organic and functional illnesses are sometimes referable to injudicious use of barbiturates. Bromide or amphetamine intoxication requires prompt recognition for effective treatment.

Alcoholic intoxication should be treated as a serious illness. The mortality rate in delirium tremens is higher than often recognized. More important than withdrawal as a causative agent is intercurrent trauma or illness in a heavy drinker. Prompt use of intravenous fluids often results in a more rapid recovery. Delirium associated with physical illness will abate with recovery from the organic disease.

The attitudes and feelings of persons concerned with patients who have organic mental syndromes need to be recognized as factors in the therapy of the patient.

Careful evaluation of the history of acute functional emotional disturbance and close attention to the verbal and behavioral productions of the patient will assist in making the correct diagnosis. The necessity for medical personnel to recognize the role of their own feelings as they arise in the management of these problems is considered paramount.

CONGENITAL IMPERFORATE ANUS

LUTHER G. BELL, *Captain (MC) USN*

FRANCIS M. SMITH, Jr., *Lieutenant Commander (MC) USNR*

CONGENITAL imperforate anus is an abnormality that, unless associated with an adequate fistulous tract to the outside of the body, is incompatible with life. This lesion is one that can be adequately treated by the general surgeon who is aware of the basic principles involved in the surgical repair of this disorder.

In the past 5 years there have been 10 patients with congenital imperforate anus treated at this hospital. To these have been added two cases seen by the junior author during this period. The 12 cases reviewed in this report are summarized in table 1.

DIAGNOSIS

Obviously the diagnosis is made by simple inspection. Physical examination of the newly born infant should identify the lesion of imperforate anus prior to the onset of any suggestive symptoms. Imperforate anus is also often detected when the nursery attendant is unable to insert a rectal thermometer. In the female an associated rectovaginal fistula may prove to be a pitfall. There have been cases on record of these going several years without being recognized.¹

PREOPERATIVE MANAGEMENT AND EVALUATION

As soon as this lesion is recognized, plans should be made at once for early surgical correction. Careful planning means full and rapid evaluation of the infant. At no time in the neonatal period is a full term infant better equipped to withstand the shock of operation than in the first few days of life. He is in a state of optimum fluid and electrolyte balance that can do nothing but deteriorate progressively with each day of delay.

The first step in the evaluation of the infant with an imperforate anus is to look for other associated congenital anomalies.² Congenital abnormalities are usually multiple rather than single. Because of the close relationship in the embryologic development of the cloaca and the urogenital sinus, associated anomalies most frequently are found in the genitourinary tract.

From U. S. Naval Hospital, San Diego, Calif.

The most common associated lesions of the genitourinary tract are rectovesical fistula and recto-urethral fistula.³ If there is a fistula between the bowel and the genitourinary tract, a voided specimen of urine may reveal gross evidence of meconium. A centrifuged sample may show lanugo hair and cornified epithelial pearls. Once this has been demonstrated, a No. 8 Foley catheter should be introduced into the bladder. A clear specimen of urine from the bladder plus a meconium-contaminated specimen of voided urine should favor the presumptive diagnosis of recto-urethral fistula.

In the female a rectovaginal fistula may occur. These are most frequently found near the fourchette.³ In patients of either sex a rectoperineal fistula may occur. In the female it opens between the rectal dimple and the vagina. In the male the opening is at the base of the scrotum or along the raphe perinei. Depending on the patency of the tract, meconium may or may not be seen to exude from this opening. In Gross's⁴ series, recto-urethral fistulas occurred in 11 percent, rectovesical fistulas in 10 percent, rectoperineal in 20 percent, and rectovaginal in 25 percent of his patients.

Other congenital anomalies may frequently be associated. Gross's series reveals that 198 of 507 patients, or 39 percent, had other associated anomalies. Some of these may take precedence over the imperforate anus. High gastrointestinal tract atresia is an outstanding example. Atresia of the esophagus with associated fistula to the pulmonary tree may co-exist with imperforate anus. Obviously, these lesions must be coped with first. Atresia and stenosis of the small bowel may be present. In short, it may be stated that the first step should be an evaluation of the patency of the gastrointestinal tract above the rectum.⁵ Perhaps the simplest method by which to obtain this information is the roentgenographic studies suggested by Wangenstein and Rice.⁶

Anteroposterior and lateral views are made with the infant in the inverted position, and a radiopaque marker is placed over the anal dimple. If air is found throughout the gastrointestinal tract and in the large bowel, the patency of the gastrointestinal tract can be assumed with but one exception, this being esophageal atresia with a fistula between the distal segment and the pulmonary tree. Other important information obtained from this study is the distance between the rectal air column and the anal dimple as identified by the radiopaque lead marker. When the end of the bowel lies far up in the pelvis it should at once suggest the possibility of a recto-urinary tract fistula.

Next, one's interest should be centered on possible cardio-pulmonary lesions. In one of our cases an infant had a completely

January 1956)

CONGENITAL IMPERFORATE ANUS

unexpanded right lung due to a developmental defect which had resulted in a lung bound down by pleural membranes. Congenital cardiac malformations are fairly frequently associated lesions. This lesion occurred in 8 percent of the patients in Gross's series and in one of ours. Careful auscultation of the heart plus routine roentgenograms of the chest should be a part of the evaluation of these infants. If a congenital cardiac lesion is found, careful attention must be given to intravascular administrations of fluid. Occasionally atelectasis may be encountered. This was observed in two of our patients. When marked, atelectasis can affect the patient's condition so severely that definitive surgery must be delayed and palliative measures undertaken.

The second step should consist of measures to prepare for operation. In the cases diagnosed early, that is, in the first 24 hours of life and in full term infants, no fluids need be administered preoperatively. However, no infant should be operated on without a "cut-down" site available for the administration of fluid and blood to combat shock. Blood should be available during the amount of 20 ml. per kilo of body weight, to be given during operation if needed. If a combined abdominoperineal or perineal approach is anticipated by the surgeon, the cut-down site should be in the antecubital area. In cases diagnosed or seen late, signs of obstruction are likely to have complicated the picture. Nasogastric suction should be instituted in these patients prior to operation. All material aspirated should be measured and taken in account in the postoperative management of fluids. In general, one may safely replace this aspirated fluid with normal saline solution in addition to the calculated fluid volume for a 24-hour period.² In those cases where an external fistula exists, an attempt should be made for thorough cleansing with normal saline. This is best done with a catheter of suitable size for the fistulous tract. The meconium can be considered aseptic for 24 to 48 hours and no antibiotic to combat gastrointestinal infection need be given preoperatively. Conversely, in late cases, it is desirable to give a broad-spectrum antibiotic 24 to 48 hours prior to operation. With the use of a suitable antibiotic one can gain not only adequate gastrointestinal tract sterilization but also have adequate systemic protection against infections. All patients should be sent to the operating room with an indwelling catheter in the urinary bladder.

OPERATIVE APPROACH

The operative technic for imperforate anus has been well documented in discussions of congenital abnormalities of the rectum to which the reader may refer.^{1,4} In view of this, we will avoid operative details and discuss the operative approach.

The average qualified general surgeon may not be called upon to treat more than a few such patients in a lifetime. As a result, although technically capable, he may err in selecting the surgical approach.

In our experience, too many patients have been operated on from the perineal route alone and too many colostomies have been done. Although both approaches are logical, the condition of the patient should dictate the choice of approach. Colostomies should be reserved for the poor-risk premature infant and for those with other congenital abnormalities of a more serious nature that take operative preference over the rectal lesion. When a colostomy is done, we suggest that it be in the left transverse colon rather than in the sigmoid area. If a genitourinary fistula is present, the bowel should be transected and the ends widely separated to prevent spillage of bowel content in the lower segment, thereby reducing the chance of urinary infection. Sigmoid colostomies may seriously interfere with the rectal pull-through when the definitive procedure is performed. This complication prolongs the operation and is an added risk to the patient. Case 12 in our group presented this difficulty. The bowel had prolapsed and had to be resected in order to complete the perineal procedure; this possibly accounted, in part, for the cardiac arrest and the patient's death.

The perineal approach is a very satisfactory one but should be used only after the problem has been well analyzed. It is suitable for the imperforate anal membrane, low rectal pouches lying within 1 and not more than 2 cm. of the skin, short perineal fistula, and low rectovaginal fistula. We believe that in every instance where the success of this procedure is in doubt, it should be decided preoperatively whether or not the patient can stand the combined procedure if necessary.

The combined abdominoperineal operation should be used where the rectal pouch ends blindly 2 cm. or more above the skin. It should be used in practically all recto-urinary fistulas and in high rectovaginal fistulas. It is also necessary in cases where the anus and anal pouch are normal and the rectal pouch ends blindly in the hollow of the sacrum.

If these principles are followed and executed with meticulous technic, the results of the correction of this congenital anomaly should continue to improve. The margin of error in performing this operation is small, but the procedure must be done correctly the first time if a good result is to be obtained.

POSTOPERATIVE MANAGEMENT

Antibiotics should be administered for from 7 to 10 days postoperatively. During the first 24 to 48 hours fluids are given intra-

vascularly and the intravenous drip is continued in event of shock. We found in our series that aspiration is a serious complication, having occurred in 3 of 12 patients. We would advise nothing by mouth for 36 hours, at the end of which time the infants have usually recovered fully from the anesthetic. The first few feedings should always be sterile 5 percent dextrose in distilled water, so that in the event of vomiting and resultant aspiration the danger of chemical pneumonitis is less than with a milk formula. Adequate sedation is mandatory in the immediate postoperative period to prevent struggling and straining which may break down the surgical correction.

An excellent formula to begin these infants on is one made of one-half part skimmed milk plus one-half part whole milk with 18 percent carbohydrates added. This gives a low fat and high carbohydrate, high protein feeding that will be more conducive to soft stools.

When the perineal suture line is well healed, cautious rectal dilations should be instituted, if necessary. These are continued until such time as an adequate function is ensured. The mother can be instructed in digital dilatation of the rectum, to be done at least three times weekly. Throughout the first year of life the condition of these infants should be followed by both the surgeon and pediatrician working in close accord. Careful attention should be given to diet and nutrition. Perhaps the most important single factor in management is the avoidance of constipation. When fecal impaction occurs in these patients, it is extremely difficult to cope with. One of our patients had an impaction so severe that surgical removal of the feces via an abdominal approach was necessary. None of our cases have been followed long enough to evaluate the anal function. However, we believe it important to caution the parents that there probably will be much to be desired in anal sphincter control.

SUMMARY

Congenital imperforate anus, in most cases discovered in the first few hours or days of the infant's life, should be surgically corrected as early as possible. The presence of other anomalies such as rectovesical or recto-urethral fistula, as well as defects in development in other parts of the gastrointestinal tract, should be ascertained preoperatively by clinical and roentgenographic examination.

The operative approach and pre- and post-operative management should be dictated by the number and types of anomalies encountered and by the age and condition of the patient. Post-operative follow-up should continue for at least a year, and should include measures to prevent fecal impaction. Conclusions

drawn from a series of 12 cases reviewed by the authors have been presented, with the aim that they will be of some aid to the military surgeons who will ever increasingly be called upon to manage these types of lesions.

TREATMENT OF PSYCHOSOMATIC DISORDERS

Every patient coming to a physician with complaints has usually interpreted them to himself in terms of specific organic pathology. He, therefore, expects a certain amount of history taking, a complete physical examination, appropriate laboratory studies, and a prescription. In the initial interview of one and one-half hours, the amount of time to be devoted to history taking and physical examination can usually be determined by the experienced clinician after the first 10 to 15 minutes. By that time, his impressions as to whether the patient's symptoms are predominantly organic or emotional in origin have been formed. In the event of frank organic disease or a diagnostic problem, a detailed medical history and physical examination is essential, and may well utilize all the allotted time. In the case of a patient with symptoms which appear to be predominantly emotional in origin, the same complete study should be carried out, but had best not be attempted in the one and one-half hours allotted to the initial interview. It is of primary importance to this situation that the latter patient be encouraged to speak freely at the first meeting, express his anxiety about his symptoms and what he thinks is the matter.

to identify and correct the deficient sanitation in the mess which caused the outbreak and which, if long uncorrected, could promote the spread of more serious food-borne disease.

2. *The surgeon telephones the Commander of Baker Company to arrange to have the entire company available, starting at 1000 hours, for questioning; to get men from the company to help with the questioning; and to arrange for an immediate inspection of the mess.*

If only Baker Company men have experienced diarrhea, it will probably be found that this company operates its own mess and messes separately.

It is of the utmost importance to question as many men of the company as possible—those “not ill” as well as those “ill” (these terms are used in their epidemiologic and not necessarily their clinical meaning). “Well” and “not ill” are used interchangeably, as are the terms “ill” and “case.” Suppose, for instance, that the vehicle for the offending micro-organism was a pudding, which was eaten by most of the men in the company, for example, 90 per cent. If only 40 men were interrogated, 20 of them from among those ill and 20 from among those well, it might well happen that none of the 20 ill men failed to eat the pudding and that only 4 of the 20 well men failed to eat it. (Note that in this group of 40 men, 36, or 90 per cent, ate the pudding and 4, or 10 per cent, failed to eat the pudding.) This looks like pretty strong evidence against the pudding, but it can be shown by the chi-square test (described later) that the association between eating the pudding and getting sick in this particular group is not a statistically significant association. Suppose, however, that instead of interrogating 40 men out of the company we interrogated 200 men and found that among 80 ill men in the group none had failed to eat the pudding, while of the 120 well men there were 20 who did not eat it. (Here again 90 per cent of the men ate the pudding and 10 per cent failed to eat it.) We would now have valuable evidence to incriminate the pudding, because it can be shown by the chi-square test that there is in these data a highly significant association, statistically speaking, between eating the pudding and becoming ill. Unless some other explanation is found to account for this association, the evidence indicates the pudding as the source of the outbreak.

The investigation must keep the men of the company away from their duties for as short a time as possible. Also, the sooner the interrogation is undertaken, the more reliable will be the answers. For these reasons, men of the company are used as interviewers. If a good questionnaire is developed, like that illustrated in figure 1, and if men of average or higher intelli-

the way to correction of the breach of sanitation. Diarrhea occurs so frequently and is so widespread in the military service that it would be impossible, if indeed desirable, to have every outbreak investigated by a specialist.

The system described in this article has been worked out through application in several diarrhea outbreaks in U. S. Army and Labor Service units in Munich, Germany, over the past few years. We found that, for efficiency and to save time for the investigating personnel and for the company under study, numerous details had to be attended to simultaneously. Full use had to be made in each outbreak of lessons learned and technics developed in preceding outbreaks. Thus, we developed a check list of things to be done, forms to be reproduced, persons to be contacted, et cetera, lest some detail be lost from sight and doom the investigation to certain failure, or obstruct and greatly prolong it. This article consists essentially of the presentation of this check list, with a brief discussion of each step and explanation of the relatively simple statistical calculations required to identify the offending food item in those instances when this cannot be done with the required certainty through simple inspection of the catalogued and compiled entries from the individual questionnaires and food sheets. It is our hope that physicians in the military service will not simply read this article, then lay it aside and be unable to find it again, but that they will use it to guide their epidemiologic investigations when confronted with an outbreak of diarrhea.

The essential steps in this system of epidemiologic investigation are presented in their proper chronological order in *italics*, and those requiring further explanation and discussion are treated in the order of their appearance. Where needed, sample forms and statistical tables illustrate the steps. To achieve greater reality in presentation, this system is applied to an imaginary outbreak of diarrhea in a mythical "Company B" ("Baker").

PROCEDURE FOR INVESTIGATION

On Saturday morning at 0800 hours several men of Baker Company appear at sick call with the chief complaint of diarrhea.

1. The medical officer in charge of the dispensary, hereinafter referred to as "the surgeon," questions patients to determine whether there is really an outbreak and, if so, to learn the approximate hour of onset in the first case.

In outbreaks of mild diarrhea, relatively few of the men affected report on sick call. Unless the surgeon has a sufficiently high index of suspicion to make inquiry, he might fail to learn that an outbreak has occurred. Any outbreak of diarrhea, regardless of its mildness and limited extent, should be investigated

to identify and correct the deficient sanitation in the mess which caused the outbreak and which, if long uncorrected, could promote the spread of more serious food-borne disease.

2. *The surgeon telephones the Commander of Baker Company to arrange to have the entire company available, starting at 1000 hours, for questioning; to get men from the company to help with the questioning; and to arrange for an immediate inspection of the mess.*

If only Baker Company men have experienced diarrhea, it will probably be found that this company operates its own mess and messes separately.

It is of the utmost importance to question as many men of the company as possible—those “not ill” as well as those “ill” (these terms are used in their epidemiologic and not necessarily their clinical meaning). “Well” and “not ill” are used interchangeably, as are the terms “ill” and “case.” Suppose, for instance, that the vehicle for the offending micro-organism was a pudding, which was eaten by most of the men in the company, for example, 90 per cent. If only 40 men were interrogated, 20 of them from among those ill and 20 from among those well, it might well happen that none of the 20 ill men failed to eat the pudding and that only 4 of the 20 well men failed to eat it. (Note that in this group of 40 men, 36, or 90 per cent, ate the pudding and 4, or 10 per cent, failed to eat the pudding.) This looks like pretty strong evidence against the pudding, but it can be shown by the chi-square test (described later) that the association between eating the pudding and getting sick in this particular group is not a statistically significant association. Suppose, however, that instead of interrogating 40 men out of the company we interrogated 200 men and found that among 80 ill men in the group none had failed to eat the pudding, while of the 120 well men there were 20 who did not eat it. (Here again 90 per cent of the men ate the pudding and 10 per cent failed to eat it.) We would now have valuable evidence to incriminate the pudding, because it can be shown by the chi-square test that there is in these data a highly significant association, statistically speaking, between eating the pudding and becoming ill. Unless some other explanation is found to account for this association, the evidence indicates the pudding as the source of the outbreak.

The investigation must keep the men of the company away from their duties for as short a time as possible. Also, the sooner the interrogation is undertaken, the more reliable will be the answers. For these reasons, men of the company are used as interviewers. If a good questionnaire is developed, like that illustrated in figure 1, and if men of average or higher intelli-

"M" Mess (mess at which the group struck by the outbreak ordinarily eats and/or presumably ate during the incubation period of the disease featuring in this outbreak).

"S" day (date on which symptoms first appeared in the first case properly classed as a part of this outbreak, not a coincidental case).

INSTRUCTIONS: Use 24-hour time, e. g., 0900 for 9:00 a. m.; 1500 for 3:00 p. m. Question every individual regardless of whether he is sick, has been sick, or remained well. Be sure he understands each question. If he IS NOT SICK or WAS NOT SICK, delete by diagonal lines and omit question 3 to 7 inclusive and question 12.

1. Questionnaire filled out on _____, 19____ at hour _____
2. _____
(Last name) (First name) (ASN) (Unit)
3. Place an X after each of the following symptoms suffered:
Sick at stomach _____ Bowels loose _____ Shaking chills _____
If so, state _____
Vomiting _____ number of movements _____ Belly gripes or cramps _____
4. Other symptoms (list them) _____

5. Which symptom appeared first? _____ Exact hour and date _____
6. Did your sickness begin suddenly? _____ Was it severe? _____
7. Are you still sick? _____ If not, how many hours were you sick? _____
8. State hour at which you ate each of the meals you had at "M" Mess on _____, 19____ ("S" day)
Breakfast _____ Dinner (lunch) _____ Supper _____
9. Indicate by an X in appropriate space which of the meals you had at "M" Mess on _____, 19____ (the day before "S" day).
Breakfast _____ Dinner (lunch) _____ Supper _____
10. Indicate by an X in appropriate space which of the meals you had at "M" Mess on _____, 19____ (the day before the day before "S" day).
Breakfast _____ Dinner (lunch) _____ Supper _____
11. Indicate by an X in appropriate space which of the meals you had at "M" Mess on _____, 19____ (the day after "S" day).
Breakfast _____ Dinner (lunch) _____ Supper _____
12. Did you eat at any place other than "M" Mess during period _____ to _____, 19____ ("S" day, the day before "S" day, and the day before the day before "S" day)? If so, indicate below where you ate, what you ate, and at what time: _____

REMARKS (Indicate to which question each refers) (Continue on reverse side):

(Signature of interviewer)

Figure 1. Individual questionnaire for investigation of diarrhea outbreak.

gence are used as interviewers and instructed beforehand in the use of the questionnaire, data can be obtained as reliable as the trustworthiness and memory of the men interviewed will permit.

To ferret out the cause of an outbreak and to determine the manner in which it operated, it is necessary to identify as many as possible of the ill persons who form a part of the outbreak in question. It is more important that no man be listed as ill when he is not than that every ill person be listed. For this reason, gross symptoms—for example, vomiting, diarrhea, and cramps—are inquired into by means of the questionnaire. Lay interviewers, making use of questionnaire forms worded in simple, readily intelligible language, can after brief instruction elicit fairly reliable answers as to gross symptoms experienced. As a further safeguard against including "false positives" as ill patients, incontrovertible criteria, such as passage of two or more stools or vomiting, are set up for determining who of the men are ill. Such qualifying criteria will, of course, miss patients with mild but epidemiologically bona fide illness—for example, those with only nausea or abdominal cramps. However, these safeguards will tend to prevent including as ill those men who, by the power of suggestion, might report as symptoms of sickness such physiologically normal phenomena as hunger pains, borborygmi, and postprandial gastrocolic reflex.

If one is obliged to choose between a small number of questionnaires carefully completed by physicians or other medical experts and a much larger number of questionnaires less accurately completed by hastily recruited and trained lay assistants, one should elect the latter, at least when one is dealing with a diarrhea outbreak, because it is necessary only to be sure that every man listed as ill really is ill, and to learn which items of food every man in the study ate. These conditions can be fulfilled through observing the precautions outlined in this article.

3. The surgeon makes the necessary changes in the questionnaire, as illustrated in figure 1, to adapt it to serve a particular outbreak, and has sufficient copies reproduced.

4. The surgeon contacts the laboratory and requests necessary culture media and service.

It is suggested that enough tubes and plates of media be obtained to culture 30 specimens, half of them for pathogenic gram-negative enteric bacilli, and half for gram-positive cocci.

5. The surgeon dispatches a messenger to pick up the culture media.

6. *The surgeon then proceeds to the mess to learn certain things about the composition and preparation of meals served during the "period of greatest probability" (explained below) and to conduct a sanitary inspection.*

The following are some of the things he does:

(a) Requests that any leftover food be placed in the refrigerator and left there, untampered with, until the surgeon indicates other disposition.

(b) Inspects the master menu for each meal served in the mess during the "period of greatest probability."

(c) Writes down the ingredients (particularly leftovers) that went into each food and beverage served at each meal during this period; when and how each food and beverage and their ingredients were prepared and handled; how long each of these items was left unrefrigerated after, or at any time during, its preparation; and any other information that might give a clue as to the possibility of pathogenic micro-organisms from human or animal sources being implanted on, or allowed to propagate in, any food or beverage or any ingredient thereof.

(d) Inquires carefully if any "extra" item of food or beverage was served at any meal during the period in question either as a substitute for, or supplementary to, foods and beverages listed in the master menu. Writes down the required detailed information for each such "extra" item.

(e) Records the identity of each person who in any way took part in preparing or serving any food or beverage served during this "period of greatest probability" and causes each such person to be subjected to such interrogation and physical and laboratory examinations (see step 13 below) as may be necessary to determine if at the time he engaged in handling any of these foods or beverages he could have carried the micro-organism of the disease featured in the outbreak.

(f) Records details of any sanitary deficiencies which he learns occurred in the mess within the past several days, *e. g.*, interruption of refrigeration, lack of hot water, lack of soap or other detergent, prevalence of flies or vermin, et cetera.

(g) Conducts a thoroughgoing sanitary inspection of the mess and premises, checking particularly such things as the temperature of the dish water; the temperature and cleanliness of the refrigerator and the condition of its contents; methods of preparing and serving food; prevalence of flies; signs of rats, mice, roaches; and personal hygiene practices on the part of food handlers.

7. The surgeon then has food sheets made and reproduced like that illustrated in figure 2.

Outbreak beginning on _____ 19 _____ among patrons of mess of _____

[illegible]

Figure 2. Food sheet for investigation of diarrhea outbreak.

Findings obtained through step 6 guide the preparation of the food sheets and dictate which items of food and drink are to be entered in its headings. Across the top of the sheet are listed the individual foods and beverages (grouped by meals) served during each meal in the "period of greatest probability," and merely the name of each meal (not items served) for 24 hours preceding that period. It is of the greatest importance that all foods and ingredients be listed which are likely to serve as the vehicle for diarrhea-producing micro-organisms. Other foods such as bread, sugar, black coffee, sugar syrups, dry cereals,

et cetera, need not be listed except when they merit suspicion in conjunction with other food. For instance, where appropriate, instead of listing "coffee," list "cream (in coffee)," and instead of listing "canned peaches," list "whipped cream (on canned peaches)."

8. *The surgeon next organizes his staff, including the men lent him by Baker Company, into two interviewing teams, one to complete the individual questionnaires, illustrated in figure 1, and the other to complete the food sheets, illustrated in figure 2.*

9. *The surgeon then thoroughly instructs the interviewers.*

He reads and explains to them the entries in the forms and impresses them that they must ask each question carefully, and must make sure that each man interviewed answers as accurately as his recollection permits, to make it possible to classify all men as "ill" or "well" (in the epidemiologic sense) and to learn which items of food and drink each man consumed.

10. *The surgeon arranges to have rooms fitted out to serve for the interviewers, with a table and two chairs for each interviewer. Those filling out the individual questionnaires should operate in a room separate from those filling out the food sheets.*

11. *As groups arrive to be interviewed, each should be under the control of a company noncommissioned officer, who directs the men quietly to enter one or the other of the interview rooms when required, and to go to the next room for the second interview when finished.*

It does not matter which interview is done first. Any person whose answers to questions 8 through 10 indicate that he has not eaten a meal at the mess during the period covered by the questionnaire is promptly dismissed and excluded from the study. However, of the group that did eat a meal at the mess during this period, both ill and well persons have to be subjected to both interviews.

12. *The surgeon supervises the interviewing while it is in progress, to ensure that the proper questions are asked and answered in the correct manner, and that the entries are correctly written.*

13. *The surgeon selects typical patients and suspected mess personnel for bacteriologic examination of their stool specimens.*

The contributions made by the laboratory toward determining the causative organism in "run-of-the-mill" diarrhea outbreaks vary greatly. Generally, the laboratory results are disappointing, possibly because the offending organism is so often ubiquitous

and indistinguishable culturally from nonpathogenic members of the group to which it belongs. Another possible reason is that an insufficiently wide assortment of culture media are used to isolate and identify every possible offending organism, whatever be the group to which it belongs. For instance, media which would promote the growth and identification of bacteria of the salmonella group might not support the gram-positive cocci, and vice versa. Often to blame is lack of sufficient competence and interest on the part of personnel taking and handling specimens and on the part of laboratory personnel examining them.

The evidence incriminating a particular food as the cause of an outbreak of diarrhea is generally at best circumstantial, but the greater the volume and reliability of such evidence, the better. The proof that the suspected item of food caused the outbreak is satisfactorily established by finding a diarrhea-producing organism in that food, the same organism in the stool, secretions, or lesions of a person known to have handled that food and in the stools of persons known to have eaten that food. However, less substantiating evidence will do. The *sine qua non* for incriminating a food is *not* that it be found to contain a diarrhea-producing organism, *nor* that this organism, if found in the food, also found to be harbored by a handler or consumer of the food. The *sine qua non* is that it be shown that none became ill who did not eat the suspected food and that all who became ill ate the suspected food. It is not necessary to prove that all who ate the food became ill, inasmuch as individual persons vary in susceptibility, some will eat more than others, and the causative organisms may be so dispersed in the mass of food that not every serving will contain them, or enough of them to produce disease. The epidemiologic investigation, therefore, can yield findings which, unsupported by laboratory findings, can indicate which item of food caused the outbreak. This investigation can at times also indicate the identity of the offending organism, how and by whom it was implanted on the food, and how, once implanted, it was able to multiply.

14. *In order to facilitate the study, the surgeon has the food sheets attached together to make one long sheet or series of long sheets.*

15. *The surgeon then studies Baker Company's completed questionnaires and classifies each man as "ill," "not ill," or "questionable."*

The severity of illness, as mentioned before, is unimportant for epidemiologic purposes. Clinically questionable cases will occasionally be observed which defy hard and fast classification. Such cases should be excluded from the study, their names and food data crossed off the food sheets, and their questionnaires removed from the others.

Having once classified a man, the surgeon must not change his classification, however strongly tempted by later findings to do so. An example would be his classification as ill of a man who reported not having eaten the food most strongly suspected of causing the outbreak. Such a discrepancy might be attributed to one of two things: that the man answered incorrectly deliberately, or because he did not understand the question, or because his memory did not serve him right; or that his was a coincidental illness and not epidemiologically a case belonging to the outbreak. Such cases which patently do not fit the pattern can, in fact, rightly be considered and reported as not belonging in the outbreak, provided care is taken to avoid bias. In other words, incorrect replying should not be assumed expressly either for the purpose of incriminating or exonerating a particular food. Furthermore the number of ill persons labeled "coincidental" cases should not be greater than corresponds to the "normal" incidence of the disease (in this study, diarrhea) among the group. In other words, out of an American company located in Germany, for example, one or even two endemic cases of diarrhea can be expected to occur, on the average, every day, including the day on which an epidemic of diarrhea occurs. But it would be bias to label five cases as "endemic," that is, "coincidental," merely in order to avoid weakening the evidence against the food most strongly suspected of causing an outbreak.

16. The surgeon numbers each man according to his place on the combined food sheets and enters this number on the man's questionnaire. A red "X" is entered in the upper right-hand corner if the man is classified "ill," and no mark if he is classified "not ill."

17. The surgeon then has each "ill" man's name on the food sheet underlined in red, and a red mark drawn through each "X" mark that indicates an eaten food in the food-item list opposite his name. The hour that each man became ill is entered above his name on the food sheet.

18. The surgeon then makes preliminary inspection of the food sheets to learn, if possible, which items and meals should be considered as most likely to have caused the outbreak.

19. The surgeon again contacts the mess.

Having drawn up a list of suspected food items on the basis of his preliminary inspection of the food sheets, he sends his sanitary inspector with this list to the mess to learn which, if any, of such items are among the leftover foods which the surgeon requested be saved; to bring back samples of any found; and to release for proper disposition any leftovers not under suspicion.

20. *The surgeon initiates necessary laboratory work.*

He causes the inoculation into the proper media of specimens of the following: available leftover suspected foods; stools from selected typical cases; and stools and swabbings from the throats and suspicious skin lesions of suspected food handlers. He has the plates and tubes properly labeled, and directs these, as well as gross specimens of any suspected leftover foods, to be properly packaged, labeled, and transported without undue delay to the hospital laboratory.

21. *The surgeon then conducts as thorough a study, including statistical analysis of available data, as is required to identify conclusively the meal and the food item causing the outbreak.*

He inspects the food sheets in order to exonerate nonoffending meals and to incriminate the offending meal and food in accordance with the following criterion: A food or meal can be considered responsible for the outbreak if everyone classified as "ill" reported having eaten it, while a substantial proportion of the group classified "not ill" reported having not eaten it.

At times a simple inspection of the food sheets will serve to exonerate certain *meals*, in that it shows that a substantial proportion of the men who became ill reported not having eaten these meals. By similar evidence, certain *foods* are exonerated. However, there is often one meal, and occasionally even one food in that meal, which fulfills—and stands out alone as fulfilling—the stated criterion. If this is the case, the surgeon is justified in considering that meal or food item to be the cause of the outbreak. More frequently no particular meal or food that completely fulfills this criterion can be found through simple inspection of the food sheet entries. Often exceptions will be found that on the surface invalidate the "perfect" evidence against a particular meal or food. For example, some persons classified as "ill" may report *not* having eaten it. Sometimes by interrogation and investigation it can be shown that some or all of these persons appearing to be exceptions actually had coincidental cases of diarrhea, not cases belonging to the outbreak. Faulty memory, or deception, or incorrect asking of the question may have caused a person to state that he did not eat the suspected food when in reality he did eat it. As previously explained, however, definite precautions must be taken in making these excuses lest bias be introduced into the study.

In the criterion as stated, it is postulated that a "substantial" proportion of the group classified "not ill" did *not* eat the food item. Obviously, if everybody ate a particular item of food there would be no basis for comparison between ill and well men with respect to eating this item, and it would therefore be impossible to adduce statistical evidence sufficient to incriminate this item.

Up to this point, no statistical treatment of data has been required except counting "ill" and "well" persons, and persons eating and persons not eating each of the meals and each of the several items of food. If, however, no one meal or food item is found to satisfy the criterion, the surgeon must test the soundness of his opinions and conclusions—that is, subject to statistical scrutiny and testing the data on which such opinions and conclusions were based.³ There is a very simple test, namely, the chi-square test,^{3,4} which is suitable for use in connection with the epidemiologic investigation of the type of outbreak under discussion.

EXAMPLE OF USE OF CHI-SQUARE TEST IN CONNECTION WITH THE EPIDEMIOLOGIC STUDY OF A DIARRHEA OUTBREAK

Number of men interviewed 300
Of whom there were classified "ill" 200 (2/3 of 300)
Of these same 300, the number eating pudding was 270 (9/10 of 300)

If eating pudding had nothing to do with causing illness

"Expected" findings would be that:

Of the "ill" men, numbering 200
9/10 ate pudding, or 180
1/10 did not eat pudding, or 20

"Expected" proportion $\frac{\text{Eaters } 180}{\text{Total } 200}$

Of the pudding eaters, numbering 270
2/3 became "ill," or 180
1/3 remained "well," or 90

"Expected" proportion $\frac{\text{'Ill } 180}{\text{Total } 270}$

However

"Observed" findings were that:

195 of the 200 "ill" men ate pudding
5 of the 200 "ill" men did not

$\frac{195 \text{ Eaters}}{200 \text{ Total}}$ "Observed" proportion

Of the 270 pudding eaters:

195 became "ill"
75 remained "well"

$\frac{195 \text{ Ill}}{270 \text{ Total}}$ "Observed" proportion

The differences between corresponding "expected" and "observed" proportions in the above illustration are of such magnitude as to raise a question as to the validity of the hypothesis that eating pudding had nothing to do with causing illness. The chi-square test would be useful in testing this suspicion, through determining the statistical significance of these differences. This test yields a value for chi-square for which there can be found in statistical textbooks^{3,4} the value for the corresponding "P" (tables 1 and 2). "P" means "probability" and is a measure of the likelihood that chance alone accounts for the differences seen between corresponding "expected" and "observed" proportions. The smaller the "P," the less this likelihood. In the example above, the chi-square (with Yates' correction) is 35.04, for which the corresponding "P" is *less than* 0.005. This is well within the range of "P" (0.05 and less), to which statistical significance is ordinarily attributed. However, a "P" within the range of statistical significance does not mean that chance did *not*

account for the difference from which the "P" was derived. It only means that a cause-and-effect relationship should be postulated between the events in question (*e. g.*, eating pudding and becoming ill) unless and until shown to be untenable on the basis of good and sufficient evidence.

TABLE 1. "Four fold table" using the statistics from the example of use of chi-square (χ^2).

Ate		Did not eat	Total
Ill	a 195 (180)	c 5 (20)	a+c 200
Not ill	b 75 (90)	d 25 (10)	b+d 100
Total	a+b 270	c+d 30	a+b+c+d 300

Numbers in parentheses are "expected" findings.

2. Formula for computing χ^2 :

$$\chi^2 = \frac{(ad-bc)^2 (a+b+c+d)}{(a+b) (c+d) (a+c) (b+d)}$$

3. Where there are small numbers, use the following formula (with Yates' correction):

$$\chi^2 = \frac{(|ad-bc| - \frac{1}{2}(a+b+c+d))^2 (a+b+c+d)}{(a+b) (c+d) (a+c) (b+d)}$$

(The symbol $||$ means the absolute value.)

TABLE 2. Table of conversion of χ^2

χ^2	P	χ^2	P
.000157	.99	1.074	.30
.000628	.98	1.642	.20
.00393	.95	2.706	.10
.0158	.90	3.841	.05
.0642	.80	5.412	.02
.148	.70	6.635	.01
.455	.50	7.85	.005

If for several foods "P's" are found by the chi-square test which are within or near the range of statistical significance, *i. e.*, 0.05 or less, consideration must be given to the possibility

that the causative agent might be a "common denominator" ingredient, *e. g.*, milk, common to several or all of the foods for which such "P's" were found. If, for example, the "P" found for coffee cream in a particular outbreak is less than 0.05, then the "P's" for other suspected items of food should be computed. Such values of "P" would be well within the range of values explainable by chance alone, most likely between 0.20 and 0.80, *unless* the same cream, or the milk from which it was taken, was served as a part of other foods or in other forms than as coffee cream. This happened in one outbreak studied by the authors, and a chi-square test was run on the basis of the observed difference between two proportions, namely, the proportion of the ill group constituted by consumers of milk or cream in *any form*, and the proportion of the well group constituted by consumers of milk or cream in *any form*. This chi-square test gave a "P" definitely within the range of statistical significance and showed that the "common denominator" was milk or cream in whatever form it was served. For the *non-milk-or-cream-containing* assortment of foods a "P" of 0.23, or 1 in 4, was obtained, which is well within the range explainable by chance alone. Thus, through actual computation the authors refuted the anticipated argument that for *any other* assortment of foods there might have been obtained as good a "P" as was obtained for the milk-or-cream-containing foods as a group.

If, however, the "P's" for several items of food are found to be within or near the range of statistical significance and yet no "common denominator" food ingredient is incriminated, consideration must be given to the possibility that as the result of improper sterilization the utensils in which these foods were prepared or served may have contaminated these foods with the causative organism.

The surgeon is not expected to be a statistician. He has merely to make a table like the one illustrated in table 1; enter in it the values for a, b, c, and d; and turn the table with these values and the chi-square formula over to any one who knows what the simple algebraic expressions mean and who can add, subtract, multiply, and divide. This person could then derive the value of chi-square, for which the surgeon could then find the corresponding "P" in the table 1 or in a textbook of statistics.¹¹ The use of a calculating machine, although not indispensable, would materially facilitate the mathematical computations and ensure greater accuracy. If the surgeon finds that more "formidable" statistical procedures are required, he should consult a statistician. There is probably one in the office of the surgeon of the next higher headquarters.

If the surgeon finds one meal only, and/or one food item only, for which the chi-square test gives a "P" of 0.05 or less, he

can, with reasonable assurance, incriminate this meal and/or food as the source of the outbreak. The same is true for any "common denominator" food ingredient.

If for no food or beverage item a "P" within or near the range of statistical significance is found, the surgeon checks the chi-square formula on each of the meals for the 24-hour period preceding the "period of greatest probability."

If for any one of the meals served during the 24-hour period preceding the "period of greatest probability" the chi-square test yields a "P" within the range of statistical significance, that meal can be incriminated. In this event it might be well to recall a sufficiently large "sample" of ill and well members of Baker Company to ask them which of the individual food items they ate at that meal. The master menu for that meal should be studied and such information should be elicited for that meal as was elicited through the mess inspection in step 6 for the meals served during the "period of greatest probability." In the absence of detailed food sheet entries for the incriminated meal, the story concerning the preparation and handling of food served at this meal may yield presumptive evidence against one particular item of food.

22. If studies to this point have turned up anything which should form the basis of "stop-gap" instructions to Baker Company, the surgeon issues such instructions to the company commander or his designated representative.

23. The surgeon then writes to the appropriate commander a special sanitary report of this outbreak with recommendations for corrective action and prevention of future outbreaks.

He should use language easily understood by a layman.

He should state such of the following as is applicable and determinable: Time of the outbreak; its magnitude in terms of percentage classified as "ill" out of the group interviewed; the fact that only the one company was affected, and that this company operates its own mess and that no other unit messes with it; the clinical picture of the typical case and roughly the proportion of mild, moderately severe, and severe cases; the meal and food item incriminated as the cause, with a brief account of supporting epidemiologic and laboratory findings; and any positive findings made on inspection of the mess, study of the master menus, interrogation and examination of food handlers, et cetera, which might indicate faulty mess sanitation or food handling practices.

24. The surgeon includes a copy of this special sanitary report and refers to it in his next monthly sanitary report.

SUMMARY AND CONCLUSIONS

The system of epidemiologic investigation described herein has been found, on trial, to be effective in identifying the offending item of food and discovering and pointing the way to the correction of the sanitary deficiency at fault in outbreaks of common diarrhea in military units. This system is characterized by the use of untrained personnel for the collection of statistical data and by statistical analyses so simple that they can be carried out successfully by medical officers who have little or no experience in epidemiology. Only a few hours' time is required for interviewing an entire company, and because the men are brought to the interview in increments no man need be kept from his duties more than an hour. It is possible to so organize and process the groups as to occasion little loss of company training or duty time.

It is believed that this system, with some modifications, would prove useful also in investigating diarrhea outbreaks attributable to a common mess in other "captive" groups, such as inmates of a prison or eleemosynary institution, or groups who could be readily reassembled for interviewing, such as patrons of a banquet or church supper and, under certain circumstances, the customers of a restaurant. It is further believed that this system could be adapted for use in the investigation of outbreaks, among such groups, of food-borne diseases other than common diarrhea.

This article does not attempt to offer a course in epidemiology, supplant the epidemiologist or the preventive medicine company, or advocate that the system of epidemiologic investigation described be employed indiscriminately. Rather it is intended to advocate the application of this system in any food-borne disease outbreak in which circumstances will permit or warrant its use.

THE VIABILITY OF TRANSPLANTED EPIPHYSEAL CARTILAGE

WILLIAM F. MacDONALD, *Major, MC, USA*

ROBERT J. BARNETT, *Lieutenant Colonel, MC, USA*

ERNEST A. BRAY, *Colonel, MC, USA*

IN SPITE of voluminous clinical and experimental research in the past century considerable doubt remains concerning the viability of transplanted bone.¹⁻⁶ There is also uncertainty as to whether or not growing epiphyseal cartilage will survive the procedure of transplantation from one area to another or from one person to another. It is generally conceded that the cells of preserved and transplanted bone die, but differences of opinion exist concerning the value of such transplants. These questions affect our clinical thinking in regard to the type of bone grafting that is most effective and the practicality of using transplanted epiphyseal plates or complete epiphyses to compensate for delay or cessation of bone growth of an extremity. In an attempt to shed further light on these processes, a number of experiments in epiphyseal cartilage transplantations were conducted in growing dogs.

MATERIAL

The purpose of this study was to repeat the experiments of earlier workers with the addition of certain refinements not available to them. All our animals were placed on penicillin and streptomycin therapy postoperatively and the factor of wound infection was eliminated. Furthermore, the transplanted epiphyseal cartilage was firmly fixed in its new position by an intramedullary wire, thus avoiding any local motion which might have an effect on cellular viability and subsequent growth.

Twenty puppies of an average age of 8 weeks were used in these studies. There were 4 general types of experiments:

1. Removal and immediate reimplantation of an epiphyseal plate.
2. Immediate autogenous transplantation of another epiphyseal plate.
3. Immediate fresh homogenous transplantation.

4. Transplantation of refrigerated and preserved epiphyseal plates.

The lower epiphysis of the radius was used in all animals, and in each case the epiphyseal plate was retained in position by an intramedullary wire. The opposite epiphyseal plate of the radius was left intact and was used for control measurements. On the operated side a needle was broken off in the metaphysis as a marker for subsequent measurement of epiphyseal growth. Preliminary studies were made on puppies to determine how much tissue required removal to eliminate the possibility of growing cells remaining and proliferating at the operative site. When this had been determined, an attempt was made in the subsequent experiments to remove all epiphyseal cartilage with as little adjacent epiphyseal and metaphyseal bone as was technically feasible. Dorsal incisions were made for exposure and only as much periosteal stripping was done as was necessary to carry out the procedure. After the operation the animals were all weight bearing without external fixation. There were no infections, but one animal died during the postoperative period. Roentgenographic studies were performed at 4-week intervals to note the appearance and state of closure of the transplanted epiphyseal plates as well as to measure the distance between the epiphyseal plates and the markers. In addition, comparison in over-all length of the radius was made with the opposite side as the control, determining by the marker whether the growth was from the transplanted epiphysis or from the one at the opposite end of the bone.

RESULTS

While the number of experimental animals was too small for any definite conclusions, the results were sufficiently consistent to warrant description. Table 1 represents a summary of the results during a postoperative period sufficiently long to be considered significant. It will be noted that where reimplantation of an epiphysis was immediately performed at its original site, the epiphysis continued to grow, although the growth was definitely retarded (figs. 1 and 2). Autogenous transplantation of epiphyseal plates resulted in no growth and early closure of epiphyseal lines. Fresh homogenous transplants and preserved frozen transplants, either autogenous or homogenous, produced no roentgenographic evidence whatsoever of cellular viability or continued cartilaginous bone growth.

SUMMARY

No conclusions can be drawn from this brief experimental study of the effects of epiphyseal cartilage transplantation. It appears to confirm, however, the extensive investigations of Haas,¹ Bisgard² and many others who believe that bone and bone-

TABLE 1. *Postoperative growth results of transplanted epiphyseal cartilage in 19 puppies*

Type of epiphyseal transplant	Number of puppies	Results
Autogenous plate reimplantation	3	All showed growth but only 20 to 60 percent of that of controls
Autogenous reimplantation of entire epiphysis	1	Growth 0.7 cm. but accompanied by disintegration of epiphysis
Autogenous plate transfer from another epiphysis	3	No growth
Homogenous plate transplant	6	No growth
Homogenous transplant of entire epiphysis	2	No growth
Frozen transplants, autogenous or homogenous	4	No growth

Figure 1. *Roentgenogram taken after reimplantation of lower radial epiphyseal cartilage plate showing intramedullary type of fixation and metaphyseal marker for growth determination.*

Figure 2. Roentgenogram of animal shown in figure 1, 7 months after operation, demonstrating by position of marker that growth has occurred at the reimplanted epiphyseal plate although it was only about 60 percent of the expected growth as compared with that of the opposite radius.

forming structures, when removed and replaced, do not continue their normal cellular activities and that direct reimplantation, fresh autogenous transfer, fresh homogenous transfer, and finally preserved grafts of any type show viability and growth in descending order. From these studies in growing dogs there is little encouragement for the proponents of epiphyseal plate transplantation for the purpose of improving growth potential following injury or disease.

SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS

ELMORE M. ARONSTAM, *Lieutenant Colonel, MC, USA*

JOHN B. PLUM, *Lieutenant Colonel, MC, USA*

SINCE 1947 there has been a progressive increase in pulmonary resection in patients with tuberculosis at Army thoracic centers. At this hospital, about 15 per cent of the patients with pulmonary tuberculosis undergo pulmonary resection as part of their over-all treatment. It is the mission of the Army to conserve or rehabilitate as many persons as possible for full military duty. The investment in each enlisted man and officer for his training and experience is an appreciable one, amounting to many thousands of dollars. Return of the man to duty rather than retirement obviates a considerable loss. Treatment of the person with tuberculosis, to be practicable economically and logistically, however, must not require hospitalization from a 2- to 3-year period as has been done previously.

PLAN OF TREATMENT

To this end, we have shortened the total hospitalization to a maximum of 14 or 16 months. Because clinical evidence indicates that present chemotherapeutic agents exert their maximum effect at about 8 to 10 months, we have aimed, in general, at a total period of chemotherapy of from 9 to 11 months. Adequate pulmonary resection is done somewhat early in the course of this chemotherapy (2 to 4 months) at a time when softer pneumonic components are no longer seen on the roentgenogram and after the bronchoscopic findings are normal. Following postoperative rest and drug therapy, a short period of hospital observation and leave ensues before the patient returns to duty. This plan of treatment has been applicable for the majority of our patients because most of them had only minimal or moderately advanced tuberculosis. From point of duration, they did not have old, long-standing, bilateral, advanced, fibrocavitary disease for which a longer and different approach to treatment must often be adopted.

RATIONALE OF RESECTIONAL THERAPY

The rationale for pulmonary resection in tuberculosis is based on pathologic, bacteriologic, and empiric evidence at hand today. Seven years' experience with chemotherapy has given us important

From Valley Forge Army Hospital, Phoenixville, Pa.

pathologic data. Antituberculosis drugs have been found unequivocally to resolve a pneumonic or lobular area of inflammation produced by tuberculous infection in a short time of 6 to 8 months. The behavior of the necrotic caseous component of the disease, however, is entirely unpredictable. Medlar¹ has observed, as have we, that liquefaction and sloughing can occur during, and even after, prolonged chemotherapy. Roentgenograms and microscopic observation of pulmonary lesions often give dissimilar impressions as to activity in the individual lesion. The similarity of resected necrotic caseous lesions from persons having had and from those not having had chemotherapy is striking. The unpredictability of the progress of these necrotic lesions is probably directly related to the recurrences or relapse of disease observed in patients treated with chemotherapy. Cavitory disease of tuberculosis pathologically has more ominous implications. True healing of cavities is rarely observed microscopically. In the past it has been difficult to culture *Mycobacterium tuberculosis* from necrotic caseous residual lesions removed from patients whether or not they received chemotherapy. Recently, Hobby and associates² by improved culture methods were able to grow *Myco. tuberculosis* in an extremely high percentage of cases. This confirms the belief held for a long time that the *Myco. tuberculosis* invariably seen on resected specimens from preoperatively proved cases are viable even after long periods of chemotherapy. That they are pathogenic for the host is probably true in a majority of instances. Not infrequently have we seen relapses in patients receiving chemotherapy for up to a year. Thus, we are extremely reluctant for these reasons to return a man with necrotic or cavitory residuals in his lungs to military duty.

METHOD OF STUDY

We have assembled pertinent data on all patients undergoing surgical intervention for proved tuberculosis. Tuberculous organisms were found preoperatively or in resected specimens from these patients. We are following them year after year to determine how they progress under our present plan of combined medical-surgical treatment. Each patient is sent yearly a detailed questionnaire about himself and his health. Those giving questionable answers concerning their health are invited back at Army expense for re-examination or, if this is impractical for the patient, the local physician or hospital is contacted for more information. Tables 1 through 3 indicate some of the pertinent results of the combined 1953 and 1954 cases.

DISCUSSION

Patients in this group are relatively young and predominantly white males. Most patients (135) had moderately advanced pulmo-

nary tuberculosis according to National Tuberculosis Association standards. A sprinkling of minimal and far-advanced cases were included (56 minimal; 15 far-advanced).

TABLE 1.

Primary operations	Number	Secondary operations	Number
Segmental resection	106	Thoracoplasty	38
Lobectomy	41	Segmental resection and thoracoplasty	1
Wedge resection	7	Segmental resection	1

Wedge resection, lobectomy, and thoracoplasty	1		
Segmental resection, wedge resection, and decortication	1		
Total	206	Total	54

For the most part these were parenchymal pulmonary problems, pleural problems having been infrequent (6 decortications in the 2 years). Most patients had resections to eliminate a necrotic or cavitory residual. The indications for operation have changed little in the past 2 years. A comparison of the types of operations performed shows a predominance of segmental resections. Experience here as well as elsewhere has shown that single or multiple segmental resections can adequately remove significant caseous or cavitory residuals. In a large number of patients (26 per cent), fine gross residual disease has been left in the form of scattered tiny nodules in the remainder of the lung and mediastinal lymph nodes because one cannot resect all of a patient's tuberculous lesions. We resected the larger caseous nodules, those beyond a few millimeters in diameter, as well as the cavitory residuals,

conserving as much lung tissue as possible. We have elected to explore and resect the pulmonary lesions first rather than perform a first-stage thoracoplasty as an initial procedure. In 1953, a large number of secondary thoracoplasties were performed in the belief that *perhaps overdistention of the remaining lung had a deleterious effect on pulmonary function and might lead to reactivation of disease.* This has not been borne out clinically.

In 1954, secondary thoracoplasty was performed only for space problem, persistent leaks, or fistula. Generally, the first rib was stripped, an apicolysis done, and parts of the second, third, and fourth ribs were removed as needed, leaving the transverse processes. Since this became standard procedure in 1954, we have had no complications from this operation, and no deformity. No evidence as yet of disease reactivation or pulmonary function

loss has become apparent in patients not receiving a secondary thoracoplasty following segmental resection.

Multiple procedures have been performed frequently; however, we are convinced that the inclusion of a thoracoplasty simultaneously with resection increases the risk of complications appreciably, and it is to be avoided except in the most suitable good-risk case. Seventy-eight per cent of our cases were uncomplicated. A comparison of the complication rate of each year is interesting. In 1953, only 70 (75 per cent) of the 94 primary operations were uncomplicated. In that year, there was one death. Anesthetic difficulties produced cerebral anoxia and eventual death. In 1954, 91 (81 per cent) out of 112 primary operations were uncomplicated, and no deaths occurred. We believe this represents a considerable improvement in technic of anesthesia, surgical judgment, and active postoperative care. The decrease in complication rate occurred at a period when our staff was reduced from four to two men, indicating that a tight, closed staff of trained personnel can probably decrease its complication rate. Another factor to be considered is that in 1954, thoracoplasty was combined with resection in only four instances. In 1953, this combination occurred 14 times, resulting in a total of 11 complications occurring in 6 of the patients. In 1954, in the four combined operations, there were only 5 complications, all of which occurred in one patient.

Persistent air leaks lasting over 2 weeks, although few in number, occurred in patients having segmental resections and in one having a lobectomy. Space problems were observed after both lobectomy and segmental resection. Bronchopleural fistula was a minor problem, most frequently occurring following a lobectomy. After lobectomy, four out of five fistulas occurred in 1953, and two out of three in 1954. All leaks, fistulas, and space problems, with one exception, were successfully treated.

Atelectasis was considered a complication when it involved a lobe or more and required use of the bronchoscope. Vigorous postoperative care has largely prevented development of this condition.

Because of rapid turnover in laboratory personnel and due to limits imposed by workload and space, we were unable to get as many positive cultures and smears from resected specimens as we would have liked. It is striking, however, how many times cultures were positive when smears and stains were negative. Cultures from 8 resected lesions in 1953, and from 9 in 1954, were positive although stains and smears had been negative. We have arbitrarily grouped the patients into those with only active lesions (pneumonic processes—4 cases), those with moderately active lesions (mixed lesions—200 cases), and those with apparently burned-out

or fibrosed lesions (inactive—1 case). Our patients had predominantly moderately active lesions.

Postoperative chemotherapy has varied with the problem at hand. We aim at giving a total of from 10 to 11 months of drug therapy pre- and post-operatively, prolonging therapy slightly in patients with far-advanced or relatively active disease, particularly when persisting after several months of preoperative therapy.

In 1953, functional results were unsatisfactory in three patients. One was discharged with a persistent bronchopleural fistula. Two patients had somewhat unsatisfactory shoulder motion due to the effects of thoracoplasty. Of the latter, one is on active duty in the Army, and one is practicing law full time. In 1954, no patient had poor functional results.

We have been able to follow 200 patients—88 of the 94 operated on in 1953 and 112 of the 1954 patients. In 195 patients, we have found no evidence of recurrence or reactivation, and we believe that they are fit for military duty or gainful employment. Of the other five patients followed, one has a bronchopleural fistula; one is hospitalized for schizophrenia (however, his tuberculosis is arrested); one is being treated for reactivation of disease in the contralateral lung; one died in a train accident; and one patient died as a result of cerebral anoxia during operation.

Our policy is to return patients to duty or temporarily retire them after completion of treatment. Thus far, we have had no evidence of relapse in those patients doing military duty or gainful civilian work.

CONCLUSIONS

It seems from the follow-up data available that pulmonary resection is effective and that to date recurrence of tuberculosis has not been a problem. Further effort must be made to reduce operative and postoperative complications, particularly that of poor functional results.

That surgical therapy can be performed with acceptable, non-disabling morbidity has been demonstrated; however, we are convinced that resection can be safe and effective only in an optimum setup with the best of equipment and trained personnel in medicine, surgery, anesthesia, nursing, and physical medicine.

HYALURONIDASE INSTILLATION IN TREATMENT OF GANGLIA

A Preliminary Report

JAMES B. ANDERSON, *Major, USAF (MC)*
JOHN A. BOLLINGER, *Captain, USAF (MC)*

FINDING a simple method of treating a ganglion of tendon sheath or joint capsule has remained a perplexing problem of considerable interest to the military surgeon who, because of the high incidence of the lesion in people in the military age group, is more frequently confronted by it than is the civilian physician. A troublesome ganglion is found more often in those whose occupation requires optimal use of tendons and joints of the wrist. Selection of a method of therapy is complicated by the military surgeon's obligation to conserve manpower and his realization that adequate surgical excision will result in the loss of many man-hours for each patient. This preliminary report describes a simple method of treating this condition.

ORIGIN OF GANGLIA

Bunnell¹ is of the opinion that a ganglion arises from a tendon sheath or joint capsule but does not communicate with the synovial cavity. Others believe that the ganglion arises as a herniation of the synovial membrane or the joint sheath space. In support of Bunnell's conclusions on pathogenesis, some authors have found that connective tissue undergoes proliferation and mucoid degeneration with the formation of numerous small cysts that eventually coalesce into a ganglion with little or no synovial lining.^{2, 3}

METHODS OF TREATMENT

Forceful disruption of the ganglion by striking the lesion with a book not only has been ineffective, but seems to be a crude and hardly professional approach to treatment.

Surgical excision has been the treatment of choice. If one accepts the theory of origin of Carp and Stout,³ adequate surgical excision requires not only removal of the ganglion, but also stripping of the adjacent sheath or capsule to preclude recurrence. Such surgical excision usually eradicates the ganglion,

but postoperative swelling and necessary immobilization prevent the patient from carrying out his work competently for a period of 2 to 3 weeks. Another complication of surgical treatment is keloid formation. Recurrence following surgical excision is reported as from 15 to 33 percent.⁴

Among the nonoperative methods of therapy, the injection of sclerosing agents into the ganglion has been uniformly unsuccessful.⁴

Injection of hydrocortisone acetate has been successfully employed by Becker⁵ in eliminating or reducing 30 ganglia; 26 disappeared, while 4 became small and asymptomatic.

Hackel⁶ recently published a preliminary report on the use of hyaluronidase injections for ganglia with considerable success. He postulates that the mucoid substance of the ganglion is of mesenchymal epithelial origin and that hyaluronic acid is responsible for its characteristic viscosity. Following admixture with hyaluronidase, a "break-down" or "degradation" occurs, resulting in a marked reduction of viscosity as measured by the Ostwald viscometer.^{6,7}

On the basis of the preliminary reports just mentioned, and the stimulus of the large number of patients with ganglia seeking treatment at the Air Force Clinic of this hospital, an evaluation of hyaluronidase instillation was undertaken. Results of treatment of 81 consecutive patients with ganglia are reported.

TECHNIC

One half to one milliliter of 1 percent procaine was mixed with 500 turbidity reducing units of hyaluronidase and instilled into the cyst through a 19-gauge needle whose bevel had been shortened to facilitate injection of all the hyaluronidase into the cyst rather than part of it into adjacent tissue. Insertion of the special needle was preceded by a small intradermal wheal of procaine hydrochloride. Aspiration of pathognomonic xanthochromic viscid mucoid material was carried out to confirm (1) the clinical impression of ganglion and (2) the location of the tip of the needle in the cyst cavity. (One tumor was eliminated from this series by this technic, because whitish material was aspirated; subsequent microscopic examination of the surgically excised tumor afforded a diagnosis of "rheumatoid nodule." Without aspiration, this case would have been a statistical failure due to faulty diagnosis.)

Thirty-nine patients were males and 42 were females. Eight patients (9.9 percent) had recurrent ganglia following previous surgical excision. Occupation of each patient and presenting site of the ganglia are listed in tables 1 and 2. Of the 81 patients, 46 were between 21 and 30 years of age, and 21 were between 31 and 40.

TABLE 1. *Occupations of the 81 patients*

Occupation	Number
Office (typing, clerical, or filing)	28
Housewife or waitress	25
Mechanic or carpenter	14
Student	4
Musician	3
Nurse	3
Manual labor or athletics	2
Telephone operator	2

	Foot, dorsal	2	
Total			81

Single injections sufficed in 68 patients. Two injections in eight, three injections in two, and four injections in three patients were carried out. Multiloculation or faulty technic may have necessitated more than one injection. Immediately after instillation of hyaluronidase, the swelling softened and the contents could be easily aspirated or expressed by pressure. Following the injection each patient was returned to normal activity with only elastic bandage compression of the site until the following morning. On re-examination in 24 hours, the swelling was usually absent. If, however, residual swelling persisted, further injections were carried out at intervals of several days.

RESULTS

Of the 81 patients, 67 (82.7 percent) responded completely. Six of the 14 in whom treatment failed had much smaller tumors which

did not feel cystic after treatment. Five patients stated that the residual swelling had become asymptomatic. A summary of the length of the follow-up period and the recurrence rate is given in table 3. In two patients, residual thickening was explored and surgically excised. A cystic ganglion was not grossly discernible in either of these specimens. Microscopic examination disclosed "thickened fibrocollagenous tissue" in one and "an obliterated cyst retaining an epithelial lining" in the other. These findings suggest that after hyaluronidase dispersion of cyst fluid, the walls collapse, become adherent, and are replaced or coapted by fibrous tissue. Such obliteration is proportional to the extent of disruption and evacuation of the ganglion. Complications were encountered, but these were inconsequential, requiring symptomatic treatment and apparently not materially detracting from the gratifying result. One patient developed a small hematoma which resorbed spontaneously, and 3 developed a nonspecific tenosynovitis, 2 of whom required plaster immobilization, responding to treatment within 2 weeks or less.

TABLE 3. *Follow-up and results of hyaluronidase instillation into ganglia in 81 patients*

Follow-up interval (months)	Number of cases	Number of recurrences
Over 12	9	2
6-12	26	5
3- 6	27	7
1.5-3	19	0
Total	81	14*

*Of the 14 refractory ganglia 13 were obviously refractory during the first three months of observation, and one within six months.

Those ganglia that ultimately recurred gave evidence in the first few months that they would be refractory, 13 of 14 recurring within 3 months. In the 8 patients whose ganglia had been surgically treated elsewhere, recurrence after surgical excision was noted within 3 months. If resolution is not obtained within 2 or 3 months, surgical excision can be carried out without further delay.

Although treatment by hyaluronidase instillation resulted in some failures, results in 81 patients appeared to be as effective (83 percent) as excision (67 to 85 percent). It did afford, however, a method for those who declined surgical treatment or for those who could ill afford loss of working time.

SERVICE ARTICLES

THE SECRET OF SUCCESS

WARNER F. BOWERS, *Colonel, MC, USA*

DISRAELI once said, "The secret of success is constancy of purpose." Unfortunately, owing to the individual variations among us, these eight simple words carry different implications and connotations depending on our backgrounds and past experiences. Consequently, it is necessary for us to define what we mean by success, what comes to mind when we speak of constancy, and what we accept as our purpose. It has been said that intelligent men always agree once they know what they are talking about, and I'm sure you will admit that most of our arguments and discussions are made necessary because we have failed accurately to define our terms of reference. The art of communication is a difficult one because of semantic variations and nuances of connotation.

Let us first discuss what we mean by success, and I suspect that were we to poll this audience, or almost any group of Americans, the preponderance of definitions would hinge on bank account or other evidence of material wealth. The "have" nations as compared to the "have nots," tend to place high valuation on what can be measured, weighed, or held in the hand, and while this is not necessarily bad, there is a tendency to neglect the more intangible factors which go to make up success. Certainly all of us can point to persons who have had great material success and yet are extremely poverty stricken in their interpersonal relationships.

There is in all of us an impediment to perfect happiness: namely, weariness of the things which we possess and a desire for the things which we have not. Possibly success and happiness are not exogenous and based entirely on material possessions but they may be endogenous, arising from within as a result of such elements as maturity of reaction, equanimity, constancy of goal, and well-rounded self-development. Can we not agree that success has two general components: the exogenous, depending on the acquisition of enough material goods so that we and our families can have all of the necessities and some of the luxuries, and the endogenous, depending on sufficient personal self-development so that we can act and react in as

Presented at graduation exercises of Army Medical Service officer orientation class at Medical Field Service School, Brooke Army Medical Center, Fort Sam Houston, Tex., 12 August 1955.

From Brooke Army Hospital, Fort Sam Houston, Tex.

nearly an adult, mature manner as possible? The dictionary defines success as the degree of attaining one's desired end, and consequently we may have to leave "success" at this point until we consider "purpose."

First, however, let us examine our concept of "constancy." The word itself means steadfastness, firmness of mind, and freedom from change, that carries the unfortunate overtone of rigidity and immobility. It is all very well to stand steadfast as a rock, but you may get covered by moss. I like to think of constancy as dynamic rather than static, as changing with circumstances and situations, but always aimed in the predetermined direction. Our concept of constancy will depend somewhat on the type of goal or purpose that we select. If our goal is easily attained and too limited in scope, we find ourselves constantly in the necessity of setting up new goals as the old ones are reached. We should think, therefore, of a high purpose or ultimate goal toward which there are many lesser goals or steppingstones, but all tending toward the final end result.

Unless we have a correlated and integrated plan, we progress from crisis to crisis by erratic rushes, we explore too many blind alleys and waste too much time retrieving lost ground. Too few of us take time to consider such matters. All of us should spend a few moments each day in orienting ourselves with our goal, in thinking noble thoughts, and in taking stock of ourselves. This is not sentimentality but very hardheaded practicality.

One of the most difficult things in life is acquiring the ability to get along with our fellow men, and too often the phrase "getting along with people" carries the connotation of spineless appeasement, blind agreement, and fear of antagonizing anyone. Such vacillation is completely unacceptable and incompatible with a well-conceived goal. First, it must be realized that it is impossible to agree with everyone, please everyone, and make everyone like you. It is not even desirable.

We must carefully set our own goal, aim our actions toward it, and let the chips fall where they will so that we can live at peace with our own consciences. This is called integrity and is a highly desirable trait to be cultivated. In this vein, William Ellery Channing has said, "Whatever you may suffer, speak the truth. Be worthy of the entire confidence of your associates. Consider what is right as what must be done. It is not necessary to keep your property, or even your life, but it is necessary to hold fast to your integrity." In this day of "brainwashing" and "turncoats" it is essential that we emphasize integrity of character. How different would be the future of many young officers and soldiers had they appreciated this principle.

Too great rigidity and inflexibility is just as bad as too great tolerance. Plato said, "For every good there are two evils; the extremities in either direction." This, of course, is a paraphrase of the Socratic doctrine of the golden mean. Even tolerance is bad in its extreme form. An example of too great tolerance is the Buddhist philosophy that all is truth or some facet of truth. By this concept, untruth is but the backside of truth and therefore simply a phase of truth. Dishonesty is simply the other side of honesty, and therefore what may seem as cheating and dishonesty to us may simply represent a variant of honesty to others.

Intolerance, on the other hand, may keep you in continual turmoil. For example, certain recent events and happenings may not be entirely to your liking and you may find yourself in a situation of which you do not entirely approve. Vain struggle against circumstances may needlessly batter you without contributing to your goal. Epictetus said, "Ask not that events should happen as you will, but let your will be that events should happen as they do, and you will have peace." This statement requires some careful thought and simply suggests that we rock with the punches and don't fight the problem. Eleanor Roosevelt has turned a neat phrase in this regard. She said, "It is not that I have so much energy, but just that I never waste any of it in indecision or regret." In other words, know where you want to go and be on your way. An interesting variation of the idea of a goal is expressed in the philosophy of Chang Kuo Lao, one of the eight Chinese immortals. He is always depicted as riding his mule facing backwards, because he felt that it makes no difference where you are going since all that really counts is how you react along the way.

Pain is the appetizer which makes pleasure more palatable. The snow-capped mountain may seem a jagged crag from the north, while it looks like a soft snowball from the south. Yet it is the same mountain; only the viewpoint has changed. The various vicissitudes of life are tools with which one's character is shaped, and mortals are placed on earth to develop character, so that whether a man has good fortune or bad is relatively unimportant. It is only his reaction to that fortune which counts. The man who suffers adversity and reacts in a proper way has developed his character in such a fashion that he has achieved a net asset, so that in the end he has been as fully benefited as though he had good fortune. Wealth and poverty are but two forces by which character is shaped, and not success and failure in themselves. Therefore, co-operate with destiny to strengthen character by whatever experience life has to offer, turning each event to good account in your favor. When we speak of turning events to your own ends and getting as much out of circumstances as you can, this may at first glance seem selfish, but such is

not the case. No man can be called selfish who advances his neighbors at the same time that he elevates himself.

This brings up the concept of loyalty. Your first and most important loyalty is to yourself and the things for which you stand. Naturally, then, you feel loyalty toward others who are honestly striving to do the best they can with the attributes they have been furnished. More generally, you owe loyalty to your government as long as it shows integrity and progress toward an acceptable goal. If these are not present, your loyalty as a citizen makes it mandatory that you play your small but important role in a corrective way at the polls. In other words, you have a proper niche to fill and it is your responsibility to fill it to the best of your ability so that you and your neighbor may profit thereby. In a more special way, those of you who are physicians owe a great duty toward and loyalty for your patients. Your patients have a right to expect that you will show complete honesty, integrity, faithfulness, truthfulness, and skill in all your dealings. Please note that I mentioned skill last, because too often we substitute mechanical and technical skill for medical wisdom. Many of us have knowledge, but what we need most is the wisdom to use that knowledge. Knowledge is static, whereas wisdom activates knowledge to make it dynamic and useful.

From what has been said, I hope you will have arrived at the conclusion that a suitable goal is the highest possible development of all the faculties and capabilities with which you have been endowed, and I hope you will agree that this is not a selfish goal, because it implies that you will assist others in their quest for development. More simply stated, this means that we should strive by all means at our command to become mentally mature, emotionally stable, well-integrated adults. Kung Fu Tse, whom we know as Confucius, has stated that a gentleman has nine aims: to see clearly, to understand what he hears, to be warm in manner, dignified in bearing, faithful in speech, painstaking at work, to ask when in doubt, in anger to think of difficulties, in sight of gain to remember right. A more modern and scientifically stated definition of maturity is that of Doctor Edward Strecker, who said that the really mature person possesses: ability to stick to a job; reliability, giving more than is demanded; persistence against obstacles; power of decision; determination to succeed and will to live; co-operativeness with others; and adaptability to time, place, and other people.

You are about to enter on a period in your life which may not have been entirely of your own choice and toward which you may not have completely unmixed feelings. We urge you to approach this with as mature and adult an attitude as you can, attempting to turn the situation to your advantage from the stand-

point of personal development. The attitudes and mannerisms which you are developing now will mold your future success, and we urge you not to sell yourself short. All of your patients should be treated just as if they were your most important private patients, and any duty you are asked to undertake should be completed according to your very best ability. Abraham Lincoln said, "I like to see a man proud of the place in which he works; I like to see a man work so that the place is proud of him."

We wish you well in your coming assignments and hope that you will be as proud of us as we are to have you with us.

Some hospitals provide the doctor with a comfortable chair, while the patient is given a cheap, inferior, uncomfortable stool. This has a significance beyond the provision of comfort for the physician. It implies his superiority and the patient's inferiority. Sometimes this may be therapeutically advantageous, because it gives the doctor prestige, but sometimes it is a disadvantage. Prestige and rapport aid suggestion, and make it easier for the patient to accept the doctor's advice; but rapport is not dependent on prestige. Indeed the doctor's prestige may hinder the formation of rapport, if the patient associates prestige with the idea of inaccessibility.

—AINSLIE MEARES, M. B., B. AgrSc. Melb., D. P. M.
in *Lancet*, p. 593, Sept. 18, 1954

The great strength of the physician rests not in his degree, his training, his license to practice, nor his experience—his strength is the man that he is. What is the most important question to be asked concerning a professional colleague—is it his school, his hospital background, his associates, or even his honors? It is none of these, the great question is "What kind of a man is he"? The other things are important, yes, some even necessary, but the test of the man is the man.

REPORTING INFLUENZA AND ACUTE RESPIRATORY INFECTIONS

[illegible][illegible]

2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024, 2025, 2026, 2027, 2028, 2029, 2030, 2031, 2032, 2033, 2034, 2035, 2036, 2037, 2038, 2039, 2040, 2041, 2042, 2043, 2044, 2045, 2046, 2047, 2048, 2049, 2050, 2051, 2052, 2053, 2054, 2055, 2056, 2057, 2058, 2059, 2060, 2061, 2062, 2063, 2064, 2065, 2066, 2067, 2068, 2069, 2070, 2071, 2072, 2073, 2074, 2075, 2076, 2077, 2078, 2079, 2080, 2081, 2082, 2083, 2084, 2085, 2086, 2087, 2088, 2089, 2090, 2091, 2092, 2093, 2094, 2095, 2096, 2097, 2098, 2099, 2100, 2101, 2102, 2103, 2104, 2105, 2106, 2107, 2108, 2109, 2110, 2111, 2112, 2113, 2114, 2115, 2116, 2117, 2118, 2119, 2120, 2121, 2122, 2123, 2124, 2125, 2126, 2127, 2128, 2129, 2130, 2131, 2132, 2133, 2134, 2135, 2136, 2137, 2138, 2139, 2140, 2141, 2142, 2143, 2144, 2145, 2146, 2147, 2148, 2149, 2150, 2151, 2152, 2153, 2154, 2155, 2156, 2157, 2158, 2159, 2160, 2161, 2162, 2163, 2164, 2165, 2166, 2167, 2168, 2169, 2170, 2171, 2172, 2173, 2174, 2175, 2176, 2177, 2178, 2179, 2180, 2181, 2182, 2183, 2184, 2185, 2186, 2187, 2188, 2189, 2190, 2191, 2192, 2193, 2194, 2195, 2196, 2197, 2198, 2199, 2200, 2201, 2202, 2203, 2204, 2205, 2206, 2207, 2208, 2209, 2210, 2211, 2212, 2213, 2214, 2215, 2216, 2217, 2218, 2219, 2220, 2221, 2222, 2223, 2224, 2225, 2226, 2227, 2228, 2229, 2230, 2231, 2232, 2233, 2234, 2235, 2236, 2237, 2238, 2239, 2240, 2241, 2242, 2243, 2244, 2245, 2246, 2247, 2248, 2249, 2250, 2251, 2252, 2253, 2254, 2255, 2256, 2257, 2258, 2259, 2260, 2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 2362, 2363, 2364, 2365, 2366, 2367, 2368, 2369, 2370, 2371, 2372, 2373, 2374, 2375, 2376, 2377, 2378, 2379, 2380, 2381, 2382, 2383, 2384, 2385, 2386, 2387, 2388, 2389, 2390, 2391, 2392, 2393, 2394, 2395, 2396, 2397, 2398, 2399, 2400, 2401, 2402, 2403, 2404, 2405, 2406, 2407, 2408, 2409, 2410, 2411, 2412, 2413, 2414, 2415, 2416, 2417, 2418, 2419, 2420, 2421, 2422, 2423, 2424, 2425, 2426, 2427, 2428, 2429, 2430, 2431, 2432, 2433, 2434, 2435, 2436, 2437, 2438, 2439, 2440, 2441, 2442, 2443, 2444, 2445, 2446, 2447, 2448, 2449, 2450, 2451, 2452, 2453, 2454, 2455, 2456, 2457, 2458, 2459, 2460, 2461, 2462, 2463, 2464, 2465, 2466, 2467, 2468, 2469, 2470, 2471, 2472, 2473, 2474, 2475, 2476, 2477, 2478, 2479, 2480, 2481, 2482, 2483, 2484, 2485, 2486, 2487, 2488, 2489, 2490, 2491, 2492, 2493, 2494, 2495, 2496, 2497, 2498, 2499, 2500, 2501, 2502, 2503, 2504, 2505, 2506, 2507, 2508, 2509, 2510, 2511, 2512, 2513, 2514, 2515, 2516, 2517, 2518, 2519, 2520, 2521, 2522, 2523, 2524, 2525, 2526, 2527, 2528, 2529, 2530, 2531, 2532, 2533, 2534, 2535, 2536, 2537, 2538, 2539, 2540, 2541, 2542, 2543, 2544, 2545, 2546, 2547, 2548, 2549, 2550, 2551, 2552, 2553, 2554, 2555, 2556, 2557, 2558, 2559, 2560, 2561, 2562, 2563, 2564, 2565, 2566, 2567, 2568, 2569, 2570, 2571, 2572, 2573, 2574, 2575, 2576, 2577, 2578, 2579, 2580, 2581, 2582, 2583, 2584, 2585, 2586, 2587, 2588, 2589, 2590, 2591, 2592, 2593, 2594, 2595, 2596, 2597, 2598, 2599, 2600, 2601, 2602, 2603, 2604, 2605, 2606, 2607, 2608, 2609, 2610, 2611, 2612, 2613, 2614, 2615, 2616, 2617, 2618, 2619, 2620, 2621, 2622, 2623, 2624, 2625, 2626, 2627, 2628, 2629, 2630, 2631, 2632, 2633, 2634, 2635, 2636, 2637, 2638, 2639, 2640, 2641, 2642, 2643, 2644, 2645, 2646, 2647, 2648, 2649, 2650, 2651, 2652, 2653, 2654, 2655, 2656, 2657, 2658, 2659, 2660, 2661, 2662, 2663, 2664, 2665, 2666, 2667, 2668, 2669, 2670, 2671, 2672, 2673, 2674, 2675, 2676, 2677, 2678, 2679, 2680, 2681, 26

[illegible][illegible]

The importance of determining the prevalence of B-type virus infections^{1,2} was also stressed in the cited instructions. In any outbreak, the pooled sera should be first tested for influenza, and if negative, the sera from suspect or patients should be retested for influenza B antibodies. Because B antibodies may not achieve maximum levels until about 14 days after the onset of illness, it is well to include in addition to the 4- to 10-day blood sample, one taken from 14 to 21 days after the onset of the illness.

From Office of the Chief Historian and Chief Curator, National World War II Museum, Department of the Army, Washington, D.C.

RESPIRATORY INFECTIONS OF UNKNOWN ETIOLOGY

The Department of Virus and Rickettsial Diseases, Walter Reed Army Institute of Research, Washington, D. C., is actively engaged in continuing studies to isolate viruses from patients with respiratory diseases whose etiology is unknown. Any outbreak of respiratory disease in which the cause seems to be neither influenza nor RI-group infection should be reported promptly to the respective Surgeon General so that study can be made. Of special interest are patients with primary atypical pneumonia in whom cold agglutinin or streptococcus MG agglutinin tests become positive.

All six Army area medical laboratories; the 406th Medical General Laboratory, Tokyo, Japan; the USAREUR Medical Laboratory, Landstuhl Medical Center, Germany; the Tropical Medical Research Laboratory, Puerto Rico; the Army Medical Research Laboratory, Kuala Lumpur, Malaya; and the Hawaiian Medical Laboratory are prepared to carry out tests for influenza and RI-type virus and assist in these studies.

THE EDUCATED PHYSICIAN

A doctor must be well educated, and that does not mean merely stuffed with knowledge, but capable of understanding in the sense that Lord Morley meant when he said the mark of an educated man was the ability to know when a proposition is proved or, what is often more important, when it is not proved.

A MODIFIED SCREENING QUESTIONNAIRE FOR SERVICEWOMEN

JOSEPH FRIEDMAN, *Lieutenant (junior grade) (MSC) USNR*

PSYCHIATRIC screening of women for service is a relatively new area in military psychiatry and possesses some unique features. For the most part, the psychologic questionnaire and tools used as adjuncts have been borrowed from the screening of men. This article describes the need for modification of these methods and one step that has been taken to achieve this end.

The psychiatric unit at this recruit depot has as one of its functions the assessment of women recruits. This evaluation consists of interviewing all women recruits at least once and at periodic recall until a decision is made regarding their emotional suitability for service.¹ As aids in the initial screening several materials are used, including a questionnaire designed to elicit signs of maladjustment. It is with this tool the present article is concerned.

Although the scale had originally been designed for men, the past procedure had been to use the identical list of items for both male and female recruits. For some time the feeling had been growing that in the case of women much of this material was nondifferentiating; that is, that many of the items were of limited value in sorting women into two categories, psychiatrically "clear" and psychiatrically "suspect." I therefore undertook a twofold study: (a) to measure the effectiveness of the existing scale, and (b) to make improvements if it was found lacking.

METHOD AND RESULTS WITH ORIGINAL QUESTIONNAIRE

The original questionnaires of all women who passed through the recruit depot during 1954 were examined. The responses of those who eventually became psychiatric casualties ($N = 92$) were recorded. Of those who adjusted to service ($N = 916$) every fifth record was selected ($N = 183$) and their responses were also recorded. A statistical technic was then applied to investigate whether or not the two groups tended to answer the items in a significantly different manner. The statistic considered most appropriate was the t -ratio of proportions.²

Of the 70 items, 26 were found to be significant at the .05 level of probability and 13 at the .10 level. The remaining 31 items did not approach statistical significance. While these results provided a nucleus for a scale, it was believed that, as a whole, the tool was inadequate for its purpose and that modifications would be desirable.

METHOD AND RESULTS WITH MODIFIED QUESTIONNAIRE

New questions were then derived from the interviewing techniques of the examiners. Another valuable source of material was the autobiographic sketch that women marines prepare before further interviewing as they progress through a trial at duty. Still another source were the anonymous questions these recruits submitted in response to a lecture on psychosexual factors and their implications for group living.

A pretrial of these 60 items was administered to 62 recruits, and those items that were checked once or not at all were eliminated. The remaining 55 items were then submitted to a group of 201 recruits who adjusted successfully, of which every other case was used (N-100), and to 39 psychiatric failures. Statistical analysis of the results of testing in this group of 139 subjects showed that 20 of the 55 items were significant—16 at the 0.05 level of confidence and 4 at the 0.10 level.

The 39 significant items from the original questionnaire and the 20 from the new one were then combined. Of these 59, 2 were dropped due to excessive overlap with the others. The modified scale when completed consisted of 42 items significant between the .001 and .05 levels and 15 at the .10 level (See Appendix).

Some attempt has been made to place the items into various categories, and a key has been added to aid the interviewer in noting along what lines the recruit's problems lie. These categories are: (a) stress situations, (b) interpersonal relations, (c) reactions to enlistment, (d) relations to authority, (e) somatic concern, (f) withdrawal and/or projection mechanisms, (g) mood, (h) psychopathy, (i) tension and anxiety, (j) acceptance of feminine role, and (k) miscellaneous. The questions are framed so as to require both affirmative and negative answers, thus reducing the tendency to superficially mark the list.

Should this technic prove to be clinically satisfactory, it is conceivable that an extension of its scope would be warranted. It might be possible to establish a cut-off score on the number of problems claimed and to cross-validate this on another group of women. The check list would then be considered a test, and the scores might be used to predict service maladjustment. To assess their predictive powers, these results could then be compared with the results of interviews and trials at duty.

SUMMARY

A statistical evaluation of the 70-item questionnaire was done to measure the discriminatory power of its items as applied to women. While many were significant statistically, the tool as a whole was believed to be inadequate for its purposes. Additional items were written and significance tests again run until a total of 42 items were accumulated which discriminated at least at the .05 level. An additional 15 items significant at the .10 level were also used, and a modified version of the questionnaire was evolved for servicewomen.

APPENDIX

Below are a series of questions and statements on several different topics. You are to answer "yes" or "no." "Yes" answers are represented by checking the box; "no" answers by leaving it blank. Be sure to answer as you really feel, not as you think others would answer. Your honesty is very important.

1. ____ Does rushing and being under pressure upset you?
2. ____ Are you often worried or upset?
3. ____ Do you feel that you will have trouble making good in service?
4. ____ Have you ever been fired or asked to resign from a job?
5. ____ Do you often feel tired, run down, and gloomy?
6. ____ Do you feel comfortable around new people?
7. ____ Insofar as you know, were you considered a very healthy child?
8. ____ Does being hollered at make you really upset?
9. ____ Does it seem to you that men get a better "deal" in life?
10. ____ Would you consider yourself a nervous person?
11. ____ Could you do more for your country in a civilian job than in the service?
12. ____ Do you sometimes get violently angry without good reason?
13. ____ Are you ever bothered with nervousness?
14. ____ Did your family move around enough to handicap you in making good friends?
15. ____ Do you have difficulty learning under stress?
16. ____ Did you dislike going to school as a kid?
17. ____ Do you often have trouble in getting to sleep?
18. ____ Life is best when we are children.
19. ____ Do you ever have pains in the heart or chest?
20. ____ As a kid did you feel you were often punished unfairly?
21. ____ Do you ever feel that you have more than your share of bad luck?

22. ____ Are you often ill at ease around your friends?
23. ____ Have you ever been in trouble for drinking?
24. ____ Did you ever look in a mirror and think you might be someone else?
25. ____ Do you feel that it was unfair for you to be called into service at this time?
26. ____ Were either of your parents often mean or unkind to you?
27. ____ Did you bite your fingernails often as a kid?
28. ____ All people are guilty of heavy sins.
29. ____ Usually do you prefer to be alone rather than with other people?
30. ____ Have you ever smoked reefers or taken dope?
31. ____ Do you have any particular physical or health problem?
32. ____ Does it make you uncomfortable when you haven't privacy in which to bathe and dress?
33. ____ Do you really like to fight?
34. ____ Have you had to make undue sacrifices by coming into the service?
35. ____ Do boys and men seem too fresh to you?
36. ____ Do people usually misunderstand you?
37. ____ Does most of life seem dull to you?
38. ____ Have you ever had dizzy spells or fainting spells?
39. ____ Do you resent others trying to advise you?
40. ____ Are you frequently bothered by back pains?
41. ____ Do you often feel that most of your troubles are not your fault?
42. ____ Do you have dates less often than most girls your own age?
43. ____ When you were punished, was it usually more severe than other kids got?
44. ____ In spite of what they say, people only look out for themselves.
45. ____ Do you feel that your life has been unsuccessful up to now?
46. ____ Do you consider your friends to be your equal?
47. ____ Are you ever troubled by a sick headache?
48. ____ Do you have trouble making friends?
49. ____ Will your time in the service keep you from achieving your personal goals?
50. ____ The worst thing about school was the bossy attitude of the teachers.
51. ____ Has anyone in your family ever had a nervous breakdown or been treated for their nerves?
52. ____ Do you think you were loved more by one parent than the other?
53. ____ Do people ever seem to purposely annoy you or pick on you?
54. ____ Do your hands ever tremble enough to bother you?
55. ____ Do you often get down in the dumps?
56. ____ Do you frequently drink just to get drunk?
57. ____ Have you ever held yourself back in some group to avoid being noticed?

THE MANAGEMENT OF LARGE BOWEL INJURIES IN THE KOREAN CAMPAIGN

H. HASKELL ZIPERMAN, *Lieutenant Colonel, MC, USA*

PERHAPS no greater advances in traumatic surgery have been made than those made during World War II for the treatment of penetrating abdominal trauma. In World War I the policy of watchful waiting in the management of intra-abdominal injuries was repudiated. World War II saw the adoption of principles and practices in the treatment of abdominal wounds that led to gratifying reductions in mortality and morbidity. It remained for us in the Korean campaign to refine, polish, and add to these principles the surgical knowledge and technics gained in the intervening war-free years. That the practices on which we built were solid was evidenced by our initial low morbidity and mortality. That the refinements we added were indeed worthy of adoption was indicated by an over-all reduction in mortality from 4.5 per cent in World War II to 2.4 per cent. This reduction was merely a reflection of the decrease in mortality among patients wounded in various specific regions, of which the abdomen was one of the most important.

One of the outstanding contributions to the surgical treatment of patients with abdominal wounds during World War II was that of Ogilvie,¹ who first advocated the technic of exteriorization of the wound in the colon. Second perhaps to this advance was excision of the coccyx with incision and drainage of the pre-sacral space for wounds of the rectum. These two technics alone led to the saving of thousands of lives both in World War II and in Korea.

INCIDENCE

The importance of treatment of large intestine wounds cannot be over-emphasized. Every publication on abdominal trauma caused by war injuries lists the colon, either alone or in combination with other abdominal viscera, as one of the three most frequently injured intra-abdominal organs. It is estimated that wounds of the large and small intestine together comprise about 70 per cent of all intraperitoneal damage among casualties with abdominal injuries. This is to be expected because these organs occupy a major portion of the abdomen. Specifically, in World War II, Ogilvie reported 128 wounds of the colon in 381 abdominal

From Brooke Army Medical Center, Fort Sam Houston, Tex.

casualties—an incidence of 33.6 per cent. The Second Auxiliary Surgical Group² in World War II reported 1,106 colon wounds in 3,154 abdominal casualties—an incidence of 35.1 per cent. In the Korean conflict, the Surgical Research Unit³ reported the colon injured 140 times in 402 abdominal casualties—an incidence of 34.8 per cent.

FACTORS INFLUENCING MORTALITY

By themselves, statistics on incidence do not portray the true seriousness of wounds of the colon. Not only do such wounds produce a significant mortality, but, because they occur very frequently in combination with wounds of other organs, they also contribute significantly to the death rate from wounds of these other organs. It has, in fact, been shown repeatedly that with intra-abdominal wounds mortality will vary directly with the number of organs involved.

Shock. The greatest single mortality-producing factor in the combat zone is shock. Perhaps the three major causes of shock among battle casualties in Korea were: (1) severe exsanguination due to major arterial injury; (2) extensive damage to large muscle masses such as those of thighs and buttocks; and (3) massive fecal contamination of the peritoneal cavity. That the latter was of importance also in World War II was illustrated by Bradford and Campbell,⁴ who in their report on fatalities incident to war wounds of the abdomen found that 19 of 91 deaths were secondary to shock from severe fecal contamination of the peritoneal cavity. That the presence of shock is an important, if not the most important, factor in mortality among battle casualties is shown by Wylie and co-authors,⁵ who reported a case fatality rate of only 5.5 per cent in 903 patients with thoracoabdominal wounds not in shock on admission compared to a case fatality rate of 59.6 per cent among those who were in severe shock on admission.

Several other factors, either alone or in combination, influence mortality during war. Among these are the type of warfare, the modes of evacuation, the availability and use of antibiotics, and the experience of combat surgeons.

Type of warfare. In a static war, such as prevailed for so long in Korea, high-priority surgical installations did not move frequently. As a result, they were always well organized for the reception of casualties, and a minimum amount of time was wasted from admission to operation. Furthermore, their evacuation lines and procedures were so well standardized and understood that little time was lost in sending casualties to them.

Modes of evacuation. The more rapid and atraumatic the means of evacuation, the better is the condition of the seriously wound-

ed on arrival at a surgical installation. In Korea, because of U. N. air control and the type of terrain, helicopter evacuation was frequently used. This resulted in a marked decrease in the time lag⁶ between wounding and operation as compared with World War II.

Availability and use of antibiotics. The statistics of the Second Auxiliary Surgical Group on thoracoabdominal wounds in the second World War show that coincident with the use of penicillin there was a drop in mortality of from 10 to 15 per cent. This by no means implies that antibiotics are a substitute for the application of sound surgical principles and practices in the initial treatment of casualties. Rather, antibiotics are a means of supplementing good surgical practice and extending its principles. Adequate supplies of all antibiotics were readily available in Korea and were extensively used. It became routine, in fact, for every casualty to receive penicillin at battalion aid stations, and this was supplemented, where indicated, by the broad-spectrum antibiotics.

Experience of combat surgeons. Every surgeon, both in World War II and in Korea, had to learn the principles of combat surgery by actual experience. With increasing experience, the mortality rate among the wounded on whom he operated decreased. The surgeon newly arrived in a combat zone leaves a trail of poorly débrided and infected wounds until, with continual practice, he learns to apply all of the correct principles and technics for an adequate débridement.

DIAGNOSIS

Among battle casualties with abdominal wounds, diagnostic procedures are begun with an inspection of the patient to determine the location of wounds of entry and exit. On the basis of their location and the man's position at the moment of wounding, the trajectory of the missile through the body may be determined, and the probable organ damage estimated. Where only a wound of entry exists, anteroposterior and lateral roentgenograms serve to localize the retained metallic missile and thus give valuable information with regard to its trajectory and probable organ damage. In the absence of severe associated wounds, the presence of shock and its severity conveys valuable information with regard to the multiplicity of the intra-abdominal trauma for, generally speaking, there is a direct relation between the number of viscera damaged and the degree of shock. Abdominal splinting is a valuable diagnostic aid, but unfortunately it is not an invariable accompaniment of perforated viscera. Bowel sounds are usually absent, especially in casualties with perforated hollow viscera. One must never forget the digital rectal examination and, where indicated, sigmoidoscopic examination. This pro-

cedure becomes especially important in the diagnosis of wounds of the rectosigmoid and rectal colon, for these wounds most frequently are responsible for the finding of blood in the rectum. Where all other methods of producing a diagnosis of intra-abdominal injury have failed, *débridement* of the wound tract with or without recovery of the missile may indicate whether penetration of the peritoneum has occurred. In this procedure, the casualty is prepared as if for definitive surgery. The wound tract is *débrided* and, if penetration of the peritoneum is found, a definitive laparotomy is performed. In all suspected abdominal casualties where the diagnosis cannot be confirmed, exploratory laparotomy is indicated, for in young healthy adults in the heat of combat, symptoms and signs may appear late. By using the diagnostic procedures outlined above, the findings in no more than 2 or 3 per cent of laparotomies in Korea were negative. Pearson and co-authors,⁷ however, reported that 8 per cent of explorations in 303 patients with suspected intraperitoneal wounds operated upon during World War II were negative.

TREATMENT

By the end of World War II, exteriorization of the colon for wounds was an accepted and obviously lifesaving procedure. This consisted of mobilization of the injured segment so that it could be brought through the abdominal wall without tension and held there as a loop colostomy by placing either a glass rod or suture tube beneath it and through the mesentery. A functioning colostomy was then established by either incising or unroofing the antimesenteric surface of the loop. Where the injury to the large bowel was extensive or on the mesenteric border, treatment consisted of division or resection of the wounded bowel with exteriorization of both ends as a spur for later crushing. Wounds of the intraperitoneal rectum and that part of the rectosigmoid colon that could not be mobilized for exteriorization were treated by closure of the perforation and the construction of a proximal, diverting spur type of colostomy.

In the Korean conflict the principle of colon exteriorization was adopted as standard procedure for wounds of that organ. An attempt was made to perform "closed loop" colostomies by exteriorizing the perforation and then suturing it so that the bowel could be dropped back intact and without anastomosis after four or five days. When a review of results indicated that about 90 per cent of these broke down or required subsequent opening because of obstruction at the abdominal wall, closure of the wounded loop was abandoned. At least one surgeon during World War II, Snyder,⁸ attempted "closed loop" colostomies. He believed they were successful in 90 per cent of selected patients.

While most surgeons in World War II favored the use of a spur type of colostomy for complete fecal diversion, Poer⁹ by the end of that war felt that spur construction should be abandoned because of the danger of crushing a poorly constructed spur and because he believed that the resistance developed by the local peritoneum was of such a degree as to render extraperitoneal colostomy closure unnecessary. In the Korean conflict only an occasional spur type of colostomy was constructed. Not only did we believe that local peritoneal immunity and antibiotic bowel preparation permitted intraperitoneal colostomy closure, but we considered that spur colostomies did not adequately divert the fecal stream. Instead, where a diverting colostomy was needed, we advocated, in Korea, that the bowel ends be separated by at least two inches of skin and peritoneum, either through two ends of one incision or through two separate stab wounds.

In both the Korean conflict and in World War II, the use of colostomies apparently solved the problem of how to treat wounds of the transverse and descending colon most expeditiously and with the greatest saving of life. Because of the liquid nature of the feces in the cecum and ascending colon, exteriorization of this portion of the bowel was attended by great morbidity and mortality due to skin excoriation and fluid and electrolyte imbalance. How best to treat wounds of the right colon remained controversial to the end of the second World War, and the same controversy flared anew in Korea.

Many different ideas prevailed among both British and American surgeons in World War II as to how best to handle wounds of the cecum and ascending colon. Thus, we find Welch¹⁰ quoting the Second Auxiliary Surgical Group as having an early case fatality rate of 64.7 per cent when right colon wounds were treated by right hemicolectomy and double-barreled ileocolostomy. This rate later in the war was reduced to 51.7 per cent by performing a resection of the right colon plus anastomosis of ileum to transverse colon. On the other hand, Colcock¹¹ favored the double-barreled ileocolostomy spur because he believed anastomosis was time-consuming and, therefore, added to the patient's shock. Murray¹² thought that right hemicolectomy was a lethal procedure for "battle abdomens" and favored resection of the damaged segment only, with exteriorization of the ends associated with anastomosis of ileum to transverse colon.

Because of the diversity of acceptable procedures, it was deemed unwise to recommend one procedure as standard for all wounds of the right colon in the Korean conflict. The greatest success achieved by most surgeons was obtained by right hemicolectomy and anastomosis. Unfortunately, no statistics are

available to back this up. Small perforations of the cecum were treated either by closure or by exteriorization by means of a cecostomy. I had one patient with a perforation through the base of the appendix and cecum that was treated by appendectomy and appendicostomy.

In Korea, multiple wounds of the colon occasionally presented perplexing problems in management. When two simple perforations were present at a considerable distance from each other, it was recommended that the distal one be sutured and left in situ and the proximal one be brought out as a diverting colostomy. When the perforations were close together, it was recommended that both be exteriorized as a single loop colostomy with the perforations connected by incision of the intervening bowel. When the colon injury was extensive at multiple locations, it was recommended that resection and exteriorization be performed at the proximal site and resection plus anastomosis at the distal site. When the patient's condition was such as to preclude taking the time for anastomosis, it was believed that multiple resections with exteriorization at each site constituted the quickest and simplest procedure for extensive colon wounds in multiple locations.

MORTALITY

When one considers the mortality for wounds of the colon in World War II, it must be recalled that the principle of exteriorization was being standardized and, as with any new procedure, the initial mortality was high. This was reflected in the mortality for the entire war, even though in the latter period of the war the mortality was decreased. A gratifying reduction in the mortality of colon wounds was effected in the Korean conflict as compared with World War II. Thus, in 1,106 wounds of the colon treated at the Second Auxiliary Surgical Group, the case fatality rate was 37 per cent. In Korea, 140 colon wounds reported by the Surgical Research Unit resulted in a 15 per cent case fatality rate. A personal communication from the medical statistics division of the Surgeon General's Office on the basis of as yet incomplete statistics indicates a case fatality rate of 15.9 per cent among 372 wounds of the colon and rectum in Korea. This parallels the roughly 50 per cent reduction in mortality of all wounded in the Korean conflict as compared with the earlier war.

SUMMARY

The management of war wounds of the large bowel in Korea was based on the concept that whenever possible these wounds should be treated by exteriorization. Because this mode of therapy was based on practices initiated during World War II, these practices are reviewed and the changes instituted during

the Korean conflict are presented. As a result of these modifications and of certain influencing factors, there was a reduction in mortality of 50 per cent in large bowel injuries in Korea as compared with World War II.

NEW NAME FOR ARMY GRADUATE SCHOOL

On 1 November 1955 the school component of Walter Reed Army Medical Center was redesignated "Walter Reed Army Institute of Research." Since 1950 this component has been known as "Army Medical Service Graduate School."

No change will be made in the mission of this institution, according to Major General Leonard D. Heaton, MC, USA, Commanding General of the Center. It will continue to provide medical research and professional graduate training required by the U. S. Army to fulfill its role in the national defense.

Brigadier General John R. Wood, MC, USA, Commandant of the school since May 1954, will carry on his duties under two new titles. He will be Director of the Institute and Commandant of the Institute's education and training activities.

ARMY EXPERIENCE CAN LEAD TO SECOND CAREER

In the past several months, many Regular Army Medical Corps officers who had completed over 20 years of service have retired voluntarily to accept top positions in the fields of medical teaching, administration, and research. Young medical officers should be aware that one of the most attractive features of the U.S. Army Medical Corps is this opportunity to enjoy two careers in one lifetime.

The following are only a few of the more recent retirees who have made significant contributions to military medicine and who have begun their second careers in responsible civilian positions.

* * *

DR. GEORGE E. ARMSTRONG, *Vice Chancellor for Medical Affairs at the New York University and Bellevue Medical Center, New York, N. Y.*

After serving as a private in the Student Army Training Corps in World War I, Doctor Armstrong received his M. D. degree from the Indiana University School of Medicine in 1925. In the meantime, he

enlisted in the Indiana National Guard and rose to the rank of Technical Sergeant. Commissioned a First Lieutenant in the Army Medical Corps, Doctor Armstrong served at various Army posts overseas and in the United States prior to World War II. During World War II, he served as Assistant Theater Surgeon and later as Surgeon of the China Theater. His Army career was culminated by his appointment as Deputy Surgeon General of the Army in 1947 and as The Surgeon General in 1951.

* * *

DR. WAYNE G. BRANDSTADT, *Assistant Editor, Journal of the American Medical Association, Chicago, Ill.*

Doctor Brandstadt entered the Army Medical Corps in 1930. He had received his M. D. degree from the University of Chicago in 1923. He subsequently was graduated from the Army Medical School, the Medical Field Service School, and the Command and General Staff School. In 1946, Doctor Brandstadt received his Master's degree in Public Health from the Johns Hopkins University and was subsequently certified by the American Board of Preventive Medicine and Public Health. His major assignment in World War II was as Commanding Officer of the 53d General Hospital in the European Theater of Operations. Following

World War II, Doctor Brandstadt was appointed editor of the *Bulletin of the U. S. Army Medical Department*, a post which he held until the medical publications of the Army, Navy, and Air Force were unified in January 1950. At that time, he joined the staff of the new publication, the *U. S. Armed Forces Medical Journal*, and subsequently became its editor-in-chief until his retirement in August 1953.

* * *

DR. RAWLEY E. CHAMBERS, *Mental Director for the Texas State Hospitals and Special Schools, Austin, Tex.*

Doctor Chambers began his 29-year Army career in World War I as an enlisted man with the Field Artillery and eventually rose to become the Army's chief psychiatrist. He was commissioned a First Lieutenant in the Army Medical Corps after receiving his M. D. degree from the Ohio State University in 1926. During World War II he commanded the 12th Evacuation Hospital, the 77th Station Hospital, the 7th General Hospital, the VII U. S. Provisional Hospital Group, and the 805th Hospital Center, all in the European Theater of Operations. He was appointed Brigadier General and Chief of the Professional Division in the Office of The Surgeon General in 1952. At the same time, he served as Chief Consultant in Psychiatry and Neurology.

* * *

DR. CHARLES L. LEEDHAM, *Director of Education, Frank E. Bunts Educational Institute of the Cleveland Clinic Foundation.*

A diplomate of the American Board of Internal Medicine, Doctor Leedham, a 1928 graduate of State University of Iowa College of Medicine, received wide experience at Army posts both in the United States and overseas areas. In World War II, he commanded the 48th Evacuation Hospital in the Ledo Road sector of the China-Burma-India Theater and later became Base Surgeon of the Base Section with headquarters

in Calcutta, India. While in his last assignment as Chief of the Education and Training Division in the Office of The Surgeon General, Doctor Leedham also served as Secretary of the American Medical Association Military Medical Section, and as The Surgeon General's representative on medical education to the Department of Defense, the National Intern Matching Plan, the MEND Committee of the Association of American Medical Colleges, as well as to accrediting authorities in medical educational fields.

DR. JOHN HARRY KING, *Head of the Section of Ophthalmology of the Washington Clinic and Associate Clinical Professor of Ophthalmology, Georgetown University School of Medicine.*

Doctor King received his M. D. degree from Georgetown University School of Medicine in 1934, entered the Army Medical Corps in 1935 and specialized in ophthalmology, training at Walter Reed Army Medical Center and the New York Eye and Ear Infirmary. A diplomate of the American Board of Ophthalmology, Doctor King served in the Philippine Islands, Hawaii, and Italy, as well as four tours of duty at the Walter Reed Army Medical Center. His last tour of duty there was as Chief of the Ophthalmology Service, Director of Ocular Research, and Consultant in Ophthalmology to The Surgeon General of the Army. He has written about 35 scientific articles on the eye, is coauthor of a manual of eye surgery, and is the inventor of several eye instruments.

* * *

DR. TOM F. WHAYNE, *Professor of Preventive Medicine, Department of Preventive Medicine and Public Health, University of Pennsylvania School of Medicine.*

After his graduation from the Washington University School of Medicine (St. Louis) in 1931, Doctor Wayne entered the Army Medical Corps in 1934. During his Army career, Doctor Wayne held several key assignments in the field of preventive medicine and twice was Chief of the Preventive Medicine Division in the Office of The Surgeon General. He studied at the Harvard School of Public Health from 1948 to 1950, where he earned degrees of Master of Public Health and Doctor of Public Health. He was certified a diplomate of the American Board of Preventive Medicine in 1949. He served as Military Advisor to the American Delegation to the First World Health Assembly in 1948 and to the Sixth World Health Assembly in May 1953.

CASE REPORTS

Acute Hemolytic Anemia Complicating Infectious Mononucleosis

CHRISTOPHER C. FORDHAM, III, *First Lieutenant, USAF (MC)*

INFECTIONOUS mononucleosis is a common cause for hospitalization in the armed services. The usual course of the disease is one of gradual but uneventful recovery. Among the complications which may make the individual patient a serious medical problem is the development of acute hemolytic anemia. This apparently is a rare event, there having been about 15 cases reported in the American literature at this writing.¹⁻¹⁰

CASE REPORT

A 19-year-old airman was admitted to this hospital on 19 May 1955. Though somewhat vague about his symptoms, he apparently had been entirely well until 12 days before admission when he noted the onset of malaise, fatigability, and anorexia. Several days later, he developed postprandial nausea and vomiting and sensations of chilliness and feverishness. These symptoms abated somewhat after 2 or 3 days and the patient continued to carry out his regular duties as an electrician. Because of persistent listlessness and fatigability, however, he presented himself for medical attention. He had noted no definite changes in the color of his urine or stools. There was no history of recent drug ingestion or injection, with the exception of penicillin administered 4 to 5 weeks previously for treatment of a superficial skin infection. The past and family histories were noncontributory.

Physical examination on admission disclosed a thin, pale, white youth, chagrined at the prospect of remaining in the hospital. The oral temperature was 98.2° F.; the pulse, 75; and the blood pressure, 125/80 mm. Hg. The sclerae were nonicteric, the pharynx clear. The heart and lungs appeared to be normal. The abdomen was soft; the liver edge could be felt 2 cm. beneath the right costal margin and was slightly tender; there was minimal punch tenderness over the right costal margin. The spleen could not be palpated. Slightly enlarged, nontender lymph nodes could be felt in the anterior cervical, axillary, and inguinal areas.

Examination of the initial blood specimen revealed a total white blood cell count of 16,600 per cu. mm. with a differential count of 6 percent neutrophils and 94 percent lymphocytes, 40 percent of which were atypical, showing cytoplasmic vacuolation, indented nuclei, and serrated nuclear margins. Hemoglobin was 13.6 grams per 100 ml.; and

From U. S. Air Force Hospital, Westover Air Force Base, Mass.

hematocrit, 42 ml. per 100 ml. Urine showed two-plus albumin and a few cellular elements. A serologic test for syphilis was positive with a cardiolipin quantitative titer of 1:8. Initial heterophil agglutination was 1:112; there was no absorption by guinea pig kidney. Sulfobromophthal-ein retention was 13.5 percent in 45 minutes.

During the first 2 days of his hospital stay, the patient had a moderately febrile course characterized by listlessness and anorexia, but he had no specific complaints. On the second hospital day, a peculiar phenomenon was noted. Blood obtained by routine venipuncture and allowed to clot invariably expressed serum which was discolored by hemolysis, whereas oxalated blood for hematologic study demonstrated clear plasma after centrifugation. Coombs' test at this time was negative. On the third and fourth hospital days, the patient's oral afternoon temperature exceeded 104° F. and although he remained mentally alert he was phlegmatic, denying specific complaints. On the fourth hospital day his skin and sclerae appeared slightly icteric and the serum bilirubin was 2.13 mg. per 100 ml. At that time the liver edge remained palpable and tender but the spleen could not be felt. On the morning of the fifth hospital day a repeat hemoglobin value was reported as 11.1 grams per 100 ml.; the hematocrit, 34 ml. per 100 ml.; and, for the first time, an area of hemolysis could be seen overlying the buffy coat in the oxalated blood specimen. Several hours later, a drop in the hemoglobin to 9.5 grams and the hematocrit to 30 ml. per 100 ml. was reported. The patient was placed on continuous intravenous drip, and intramuscularly administered ACTH, 40 mg. every 6 hours, was started. The next day he was clinically improved, subjectively and objectively. In vitro hemolysis remained evident in both the clotted and unclotted blood samples. The urine contained hemoglobin, but the output remained good and no crystals were observed in the sediment.

On the seventh hospital day, 2 days after the apparent onset of hemolysis, the hemoglobin reached its low point of 8.6 grams and the hematocrit, 28 ml. per 100 ml. The white blood cell count at that time was 8,000 per cu. mm. with 75 percent lymphocytes, half of which were atypical. Steroid therapy and fluids given intravenously were continued. On 27 May, the ninth hospital day and the fourth day after the onset of hemolysis, the patient had a stable hemoglobin and hematocrit, and a Coombs' test was positive. His urine output remained good and his spleen became palpable 1 to 2 cm. beneath the left costal margin. Osmotic fragility studies were normal and the reticulocyte count was 6 percent. The heterophil titer reached a maximum level of 1:448 with one tube absorption by guinea pig kidney and thereafter diminished. He was switched to cortisone orally given on the fourth day following onset of hemolysis, and the dose of this steroid was gradually reduced thereafter from its initial level of 200 mg. per day. His subsequent hospital course was one of uneventful recovery with the reversal of all abnormal physical and laboratory findings, including the cardiolipin microflocculation

rest. He was discharged from the hospital 21 June, and when seen in the clinic 3 and 6 weeks later had remained completely well.

Comment. It was clear soon after hospital entry that this patient presented clinical and laboratory features characteristic of infectious mononucleosis. Several days thereafter, an acute hemolytic process supervened, resulting in a striking reduction in the hemoglobin and hematocrit values within a matter of hours. Hemoglobinuria, reticulocytosis, and a positive antiglobulin test were demonstrated. Subsidence of the hemolytic process and uneventful clinical recovery were chronologically related to the institution of adrenal steroid therapy.

Infectious mononucleosis is one of a heterogeneous group of diseases occasionally associated with an acute hemolytic process. The term "symptomatic hemolytic anemia"¹¹ has been used to describe this relationship, implying that the hemolytic process is etiologically related to the underlying disease. Possible pathogenetic factors include autoimmune antibodies, hypersplenism, and the direct action of viruses.

The observation of hemolysis in the clotted blood specimens and its absence in the oxalated samples apparently presaged the onset of in vivo hemolysis and acute hemolytic anemia. There was a 3-day interval between this finding and the appearance of a detectable drop in the hematocrit; when the latter occurred, hemolysis could be observed in both the clotted and unclotted specimens. The significance of this observation is not understood.

Ainhum

ROBERT L. CHANCEY, *Major, USAF (MC)*

BERNARD F. GIPSON, *Captain, USAF (MC)*

AINHUM, a chronic disease characterized by the formation of a groove around the base of a digit, usually the fifth toe, leading to eventual spontaneous amputation, is unusual in natives of the United States. Jacobs and associates¹ in a review of the literature up to 1950 found 54 reported cases in the United States and presented one of their own. Most of these cases occurred in southern Negroes. We have located reports of 12 other cases since then.²⁻⁴ We wish to report another instance of this unusual condition seen in a young American Negro who spent most of his life in the Midwestern United States.

CASE REPORT

An 18-year-old Negro was admitted to the hospital 8 July 1955 with the complaint of a painful little toe of the right foot. This man was born in Tennessee. He lived there for 2 years, then moved to the Midwest where he remained until he joined the military service, 4½ months prior to hospital admission. Shortly after joining the military service he developed an "infection" of both feet. A few days later he noted pain on motion of the fifth toe of the right foot. Shortly after this he noted a small crease at the base of this toe. This gradually progressed until there was a deep groove involving the entire circumference of the base of the toe. The toe was painful, especially on walking, but the patient was able to continue with his military duties. The discomfort finally became so acute he sought medical care and was admitted to the hospital.

Family history revealed that the patient's father, one paternal uncle, and two brothers had thickening and scaling of the skin of the palms and soles. There was no other significant family history.

Examination revealed a moderately obese man who did not appear acutely ill. His blood pressure was 110/70 mm. Hg; pulse, 80; and temperature, 98.4° F. There was a deep fissure involving the base of the fifth toe of the right foot (fig. 1) but there was no evidence of any acute process involving the groove. There was hyperkeratosis of the palms and soles with a superimposed apparent dermatophytosis of the feet. The fifth toe of the left foot appeared normal. Oscillometric studies of the lower extremities were normal.

From U. S. Air Force Hospital, Lowry Air Force Base, Colo. Dr. Chancey is now at Beloit Clinic, 1146 Grant St., Beloit, Wis.

Serologic tests for syphilis and a urinalysis were negative. A complete blood cell count was within normal limits. The fasting blood sugar was 102 mg. per 100 ml., and no sickling of cells was noted at the end of 72 hours. Repeated cultures of scrapings from the feet did not reveal pathogenic fungi.

Figure 1. Appearance of the right foot on the patient's admission to the hospital. There is a deep groove in the fifth toe.

A roentgenogram of the right foot showed bony atrophy of the distal portion of the fifth proximal and distal phalanges (fig. 2).

Treatment by soaking in a 1:5000 solution of potassium permanganate produced improvement in the acute inflammation, but the groove involving the base of the fifth toe on the right foot was not influenced. Because of failure to improve on conservative treatment and because of continued pain the toe was amputated on 27 July 1955, and recovery was uneventful.

Pathologic findings

Gross. The toe measured 5.5 by 2.5 by 2 cm. in its greatest dimensions and weighed 11 grams. There was a fibrous band constricting the proximal phalanx. The top of the toe was swollen, blue to grayish in color and scaly. On sectioning, it was found that there was a fracture near the junction of the middle and distal thirds of the proximal phalanx.

Microscopic. Sections revealed severe hyperkeratosis and acanthosis of the epithelium (fig. 3). Although the constricting groove was easily recognizable on the sections there was no evidence of a definite fibrous band. In the subcutaneous tissue there were scattered agglomerations of inflammatory cells consisting mainly of lymphocytes, plasma cells,

Figure 2. The bony changes are quite evident in this roentgenogram of the involved toe, and the circumferential groove can be seen in the soft tissue shadow.

Figure 3. Low-power magnification of section taken through the constricting groove of the toe.

and macrophages. The walls of the blood vessels were thickened and the lumen narrowed, but there was no evidence of obliteration. The

toenail was normal. The bone above and below the groove showed osteolysis and chronic periostitis.

Diagnosis: Ainhum.

DISCUSSION

Many conditions have been implicated as causative factors in ainhum. Among those mentioned¹⁻⁴ are leprosy, scleroderma, syringomyelia, pityriasis rubra pilaris, syphilis, hyperkeratosis of the palms and soles, and congenital hereditary factors. In the English language literature it is generally conceded that the cause of this condition is unknown. Shaffer⁵ reported a case of ainhum in a white woman with diabetes mellitus and suggested that it was a symptom and not a disease entity. Kean and Tucker,⁶ in a review of the literature, suggested three large divisions as regards etiology, *i. e.*, infectious, constitutional, and mechanical. They concluded that the cause of ainhum is unknown and the pathogenesis unclear. The racial factor was considered important. Davis and Hewer⁷ suggested that dermatophytosis played a part. The case reported by Jacobs and associates apparently had its onset after a fungus infection of the feet. In the case reported here the annular constriction at the base of the toe occurred following the onset of apparent dermatophytosis of the feet. In addition, the patient presented here had hyperkeratosis of the palms and soles. It is probable that the occurrence of annular constrictive bands of the digits and dermatophytosis is fortuitous rather than the cause and effect.

The histologic picture was nonspecific.

This patient's findings lend further support to the suggestions that ainhum is a symptom which may occur in many conditions and is not a primary disease.

Unusual Cause of Backache

JOSEPH W. BATCH, *Colonel, MC, USA*

JOHN D. ASHBY, *Lieutenant Colonel, MC, USA*

BACKACHE is a symptom of an organic, or at times a psychogenic condition and is not a disease or a diagnosis unto itself. The complaint of backache is so common that few people reach adult life without having back complaints at some time. The etiologic factors which have been described as responsible for backache are multiple. These include congenital anomalies, developmental defects, postural abnormalities, mechanical strain, trauma, epiphysitis, infections, toxic factors, arthritis, gout, paralytic and functional neurogenic lesions, visceral lesions, muscular and fibrous tissue affections, metabolic, nutritional, endocrine, allergic, climatic, circulatory, hematologic, neoplastic, gynecologic, obstetric, and urologic lesions.¹⁻³

The following is a case of backache which recurred following an operation and is considered secondary to it. Although it is not a new cause for backache, the authors have not seen previous reports of similar cases.

CASE REPORT

A 32-year-old officer was admitted to the neurology service of this hospital 26 January 1955, as a transfer from another hospital, complaining of low back pain with radiation of pain to the right hip and down the posterior aspect of the right thigh and calf.

The patient stated that he had been well until June 1942 when he lifted a heavy crate, developing pain in his low back. His back was taped and the pain subsided after 1½ weeks. In April 1943 while on duty in Africa, he fell from a truck, injuring his back. During the same year he had malaria and has had an annual recurrence ever since. Following his fall from the truck he had acute low back pain with radiation down the right leg and was hospitalized for 5 days, receiving conservative treatment. The pain abated and he was discharged from the service 22 August 1944.

In 1946 after helping his father lift a boiler, he again experienced backache with radiation down the right lower extremity. The pain recurred intermittently after this but he was not hospitalized until May 1947 when he was admitted to a Veterans Administration hospital with the diagnosis of a herniated nucleus pulposus between the fourth and fifth lumbar vertebrae. On 21 September 1947 this herniated nucleus

pulposus was excised and a spinal fusion performed to ankylose the third, fourth, and fifth lumbar vertebrae to the sacrum. The patient obtained considerable relief from this operation and was clinically much improved. He applied for and was recalled to active duty 24 January 1952. He was free of pain until March 1954 when, while lifting some heavy equipment in Germany, he had an acute onset of back pain with radiation down the right lower extremity. He was admitted to the hospital 1 November 1954 where conservative treatment, consisting of firm bed, diathermy, massage, and exercises, was given without relief of pain. He was evacuated through medical channels to another hospital in the zone of the interior and later transferred to this hospital, arriving 26 January 1955.

Physical examination on admission to this hospital revealed a well-nourished man who walked with a slight limp and favoring the right leg. He stood with a list to the right. There was a well-healed, 6-inch, longitudinal scar slightly to the left of the midline in the lower lumbar and sacral region. The lumbar spine was semirigid and had less than the normal curve. Flexion, extension, and lateral bending were limited and caused slight discomfort. The apex of motion took place between the second and third lumbar vertebrae. Straight leg-raising tests were positive on the right at 30 degrees above the horizontal and on the left at 40 degrees, producing right calf pain. Deep tendon reflexes were obtained only with reinforcement but were equal bilaterally. The extensor of the great toe on the right was weaker than that on the left. There were no sensory or vascular changes in either lower extremity. There was no muscle atrophy or muscle spasm of the right lower extremity compared with the contralateral extremity. There was no tenderness over the posterior tibial or sciatic nerves bilaterally but marked tenderness over the right superior gluteal nerve and slight tenderness over the lower lumbar spine, most marked at the interspace between the fourth and fifth lumbar vertebrae. Admission laboratory studies, including hematology, urinalysis, and serology, were reported within normal limits.

The admission roentgenogram of the chest was normal. Roentgenograms of the lumbosacral spine demonstrated evidence of the surgically performed spinal fusion extending from the third lumbar vertebra to the sacrum. There were several areas of pseudarthrosis between the fourth and fifth lumbar vertebrae, the fifth lumbar vertebra and the sacrum, and the major bony segment extending from the sacrum up to the fourth lumbar vertebra (fig. 1).

On 31 January 1955 the patient developed a febrile course and was treated for a recurrence of malaria which promptly responded to therapy. On 18 February 1955 he was referred to physical medicine service and placed on therapeutic swimming. A myelogram on 24 March 1955 revealed a marked constriction in the frontal projection and a dorsal filling defect just beneath the lamina of the fifth lumbar vertebra with narrowing of the spinal canal to about 2 mm. (figs. 2 and 3).

Figure 1. Lateral roentgenogram of the lumbar spine demonstrating spinal fusion and areas of pseudarthrosis.

The patient was transferred to the orthopedic service on 26 March 1955 for treatment. On 31 March 1955, under general (open oxygen) ether anesthesia, the previous operation area was explored. It was found that the tibial graft previously used for spinal fusion had united to the sacrum but was ununited proximally and below to the fourth and fifth lumbar vertebrae. This bone was separated from the sacrum with an osteotome and excised along with the fibrous tissue surrounding it. This exposed two fragments of bone extending between the pedicles of the fifth lumbar vertebra corresponding to the position of its lamina. The fragments of bone were irregular in contour and freely movable. The one on the right extended to and surrounded the fifth lumbar nerve root. These fragments of bone were excised by sharp dissection. It was noted that they were compressing the dura and cauda equina. Beneath the bony fragments there was additional cicatricial tissue circumferentially constricting the cauda equina and the right fifth lumbar nerve root. This fibrous tissue was carefully dissected free from the cauda equina and

Figure 2. Posteroanterior projection of lumbar myelogram demonstrating constriction at the level of the fifth lumbar vertebra. Figure 3. Lateral projection of lumbar myelogram demonstrating marked narrowing of the spinal canal due to bony projections.

the right fifth lumbar nerve root. The fifth lumbar nerve root on the left and first sacral roots bilaterally were free. The disk spaces between the fourth and fifth lumbar vertebrae and the first sacral vertebra were inspected and injected with one-half ml. of saline and found to be intact. An H-shaped graft was removed from the posterior ilium on the right along with additional cancellous bone. The articular facets between the fourth and fifth lumbar vertebrae and the fifth lumbar vertebra and the sacrum were excised of articular cartilage and cancellous plugs of bone impacted in the defect. The H-shaped graft was placed to fit firmly between the spinous process of the fourth lumbar vertebra and the first sacral segment. Additional cancellous bone was placed about the H-shaped graft to reinforce the fusion, and the wound was closed.

Following surgery the patient was free of the back pain which had radiated down the right leg and his convalescence was satisfactory and uneventful. He was asymptomatic and returned to duty 16 June 1955.

DISCUSSION

The recurrence of pain following operation for herniated nucleus pulposus is frequently stated to be due to an extension of additional disk material from the same disk space to a herniation at another level which may have been overlooked or which developed subsequently following operation or due to cicatricial tissue which may develop around a nerve root subsequent to the surgical intervention. When disk excision is accompanied with an immediate spinal fusion, pseudarthrosis of the fusion is usually considered to be the causative factor producing the continued complaint of back pain.

Our patient had only slight backache; his major complaint was pain in his right hip which radiated down to his right calf. On re-exploration, the L4 and L5 disk spaces appeared normal to inspection and were considered to be intact when not more than 0.5 ml. of saline could be injected into them. There were multiple areas of pseudarthrosis in the previously performed spinal fusion but these were not considered to be the cause of the patient's pain. It seemed that at the time of initial exploration and fusion the major portion of the lamina of the fifth lumbar vertebra had been removed and cancellous bone placed directly on the dura as a bed for a cortical graft. This cancellous graft material produced compression and the formation of a constricting band of fibrous tissue around the cauda equina and fifth lumbar nerve root on the right, resulting in continued low back pain with radiation down the right lower extremity.

This case emphasizes the care that must be exercised in performing a satisfactory spinal fusion so that it does not act as a cause for continued backache. The advisability of performing an immediate spinal fusion at the time of performing laminectomy for displaced disk is questionable.

Where there is a recurrence of backache with or without sciatic radiation following spinal fusion, the surgeon must consider the fusion as causative in his differential diagnosis and rule it out by obtaining myelograms to determine if there is or is not compression on the cauda equina or nerve roots from the bone mass of the spinal fusion.

SUMMARY

A patient who had backache with radiation of pain down his right lower extremity was benefited initially by exploration and spinal fusion only to later develop slight backache with radiation of pain down the right calf. The spinal fusion was considered to be responsible for producing compression of the cauda equina and right fifth lumbar nerve root with a recurrence of the patient's symptoms. The patient's symptoms were relieved by a second operation.

THEORETICAL THERAPY

Are we not prone to accept a drug as effective in treatment because it ought to work rather than because it does work? Undoubtedly we are. Is there not a tendency to be convinced that because a drug reduces gastric acidity it does heal gastric ulcers, that because a drug increases cardiac output it benefits cases of heart failure, or that because a drug kills micro-organisms in a Petri dish it will kill them just as well in a living patient? The theoretical and laboratory tests for the effects of treatment are an essential part of clinical research and are responsible for many brilliant advances in therapeutics, and doctors must be on guard against being converted too readily to a line of treatment by theoretical arguments until these are supported by practical clinical tests.

Rupture of Interstitial Pregnancy With Delayed Diagnosis

ALAN DAVIDSON, *First Lieutenant, USAF (MC)*

JOHN A. HENDERSON, *Major, USAF (MC)*

COURTLAND BERRY, *M. D.*

THIS case is considered worthy of report because it concerns a patient who was operated on for a ruptured interstitial pregnancy about 25 days after it is believed rupture occurred.

CASE REPORT

A 32-year-old woman was admitted to the hospital on 12 February 1955, with the chief complaint of pain of one day's duration in the right upper quadrant of the abdomen and right side of the back. Her last menstrual period had occurred on 26 October 1954, making her 15½ weeks pregnant. She apparently had been well until 1800 hours the day prior to admission, when she suddenly developed abdominal pain. By midnight, the pain had become so severe that she had sought the aid of a local physician. The pain was described as midabdominal and radiating to the right side. The patient was unable to lie on her right side. She was given an injection of 50 mg of demerol (brand of meperidine hydrochloride), which failed to relieve the discomfort, and she remained uncomfortable throughout the night. At 1100 hours the pain became increasingly severe and the patient was admitted to this hospital.

The patient stated that since the onset of pain she had felt weak and had moderate malaise, but had at no time fainted. No vaginal bleeding or uterine cramps were noted. Past history revealed that she had had two normal pregnancies with spontaneous deliveries. She denied any miscarriages or intrauterine manipulations. Systemic review up to the present illness was entirely negative.

Physical examination revealed a thin, well-developed woman in moderate distress. Examination was entirely negative except for the following: Blood pressure, 100/60 mm Hg; pulse, 110, regular and strong. Abdominal examination revealed mild pain to deep palpation in the right upper quadrant and a mass which apparently originated from the pelvis, rose to one cm above the umbilicus and seemed to deviate to the left. There was slight tenderness in both flanks. There was no

rebound tenderness, rigidity, or muscular spasm. The liver, spleen, and gallbladder were not palpable. Pelvic examination revealed a soft, bluish, nondilated cervix. There was no evidence of vaginal bleeding. Bimanual examination confirmed the fact that the abdominal mass was the uterus, which was believed to contain a four-month fetus and a fibroid in the left cornu.

Laboratory studies revealed a hemoglobin of 8.5 g/100 ml, a red blood cell count of 2.02 million, and a white blood cell count of 18,900 per μ l with a differential of 94 per cent polymorphonucleocytes and 6 per cent lymphocytes. Sedimentation rate was 20 mm per hour. Urinalysis was negative.

The patient was admitted to the surgical ward with a possible diagnosis of acute cholecystitis. She was placed on absolute bed rest, antibiotics, and mild sedation. The temperature, which had been 100° F on admission, gradually became normal by the next day. The hypogastric and right upper quadrant pain of which the patient initially complained gradually subsided, although there was abdominal tenderness to deep palpation. She had normal bowel movements and no urinary tract complaints. On 20 February, nine days after the onset of illness, the patient complained of mild lower abdominal cramps, and some vaginal spotting was noticed for the first time. On 22 February the bleeding continued and it then became bright red for the first time. The patient developed abdominal cramps and passed some tissue which was sent to the laboratory for examination. The bleeding continued and on 23 February the patient was given a blood transfusion. The bleeding gradually subsided, although the patient continued to have intermittent abdominal pains and cramps and a passage of a moderate amount of blood for the next 10 days. On 7 March the laboratory reported that the tissue specimen was degenerating decidual tissue and blood clot. No intact villi could be identified.

Pelvic examination at this time revealed the uterus to be smaller than it had been on admission. The cervix was 50 per cent effaced and patulous, and there was mild spotting from the os. There was no pain on movement of the cervix. An intravenous pyelogram revealed a fetus lying superior to the bladder (fig. 1). The preoperative diagnosis of abdominal pregnancy, possible ruptured interstitial pregnancy, was made.

On 9 March, 27 days after her initial onset of pain, and after a transfusion of whole blood, an exploratory abdominal laparotomy was performed. In the peritoneal cavity, 300 to 500 ml of old, clotted blood were found. The sigmoid was adherent to the uterus, but was freed by blunt and sharp dissection, revealing a rent in the uterus about 2 or 3 cm in diameter (fig. 2). The sigmoid had apparently sealed off this rent and prevented bleeding from it into the abdominal cavity. Further exploration revealed the fetus lying anterior to the uterus and over the bladder. Inspection of the tubes and ovaries revealed them to be per-

Figure 1. Roentgenogram (pyelogram) with dye in bladder demonstrating fetus in transverse. Its lateral position suggests abdominal pregnancy.

Figure 2. Total abdominal hysterectomy revealing the ruptured area of a 16-week interstitial pregnancy.

fectly normal. A total abdominal hysterectomy was performed. The patient's postoperative course was completely normal, and she left the hospital in good condition on her tenth postoperative day.

Figure 3. Ruptured interstitial pregnancy: The uterus is on the left; the fetus, adherent to the superior surface of the bladder, is on the right. Tissue adjacent to fetus consists of fatty tissue and blood vessels with a very pronounced lymphocytic infiltration. No placental villi or true decidual tissue are identified.

Pathology Report

Gross examination of the surgical specimen (figs. 3 and 4) revealed a uterus measuring 8 cm in length and 6 cm in width. In the left cornu there was a large mass, dark reddish purple in color and measuring 8 cm in its greatest diameter. The mass was ruptured in one area where irregular nodules of dark reddish purple tissue were identified. Upon opening the uterus, the cervix appeared normal to gross inspection. The endometrial cavity was small and contained a moderate amount of blood clots. An amniotic cavity was identified within the large mass in the cornu.

Microscopic examination of the myometrium adjacent to this area disclosed marked swelling of the individual fibers, with a permanent decidual reaction in some areas. Large numbers of placental villi were noted. The villous processes were surrounded by blood clot and exhibited marked degeneration. The area adjacent to the gross rupture revealed degenerating fragments of decidual tissue and myometrium.

Figure 4. Cross section of uterus showing separate endometrial and amniotic cavities.

SUMMARY

In a case of rupture of an interstitial pregnancy of 16 weeks' gestation, rupture apparently occurred about 1 month prior to laparotomy. Vaginal bleeding occurred for the first time about 10 days after the rupture. At operation the sigmoid was found to be adherent to the opening in the uterus.

It's well known that every university faculty has arteriosclerosis; it is not so well known that the students have it also. —Martin T. Fischer

Multiple Hereditary Cartilaginous Exostoses With Polyposis of the Colon

PETER ZANCA, *Colonel, MC, USA*

THE combination of multiple cartilaginous exostoses and polyposis of the colon is extremely rare. A thorough search was made of the available literature and no identical case report could be found. The closest associated pathologic condition was reported recently by Plenk and Gardner¹ who described osteomatosis, an hereditary disease of membranous bone formation, in conjunction with polyposis of the colon. Nine cases of this type have been recorded.

The bone lesions in the case described herein had their origin in the cartilage cells of the epiphyseal plates; true exostoses, therefore, differ from osteomatosis, which has its origin in disturbed formation of membranous bone.

Whether the combination of multiple cartilaginous exostoses with polyposis is coincidental or is based on a combined hereditary dominant gene is unknown. The genealogy of our patient was not investigated.

CASE REPORT

A 40-year-old white woman was admitted to this hospital for removal of polyps of the sigmoid colon. For 3 months prior to admission she had complained of abdominal pain in the left lower quadrant. Past history revealed that for many years she had had multiple exostoses involving the long bones and spine.

Sigmoidoscopic examination failed to reveal any evidence of polyp formation. Routine barium enema with double-contrast air study of the colon revealed two constant, smooth, rounded, radiolucent areas; each measured about 0.8 cm. in diameter and involved the sigmoid colon. The remainder of the large bowel appeared normal (fig. 1).

A skeletal survey showed the skull to be normally developed, and there is no evidence of osseous lesions involving the cranium, facial bones, or bones of the hands, feet, or ribs. Multiple small and large sessile and pedunculated exostoses with cartilaginous tips were seen projecting into the soft tissues bilaterally on the diaphyseal side of the epiphyseal plates of the long bones. These included the tibia, fibula, radius, ulna, and femur. The bony projections extended outward away

From Tokyo Army Hospital, APO 500, San Francisco, Calif.

Figure 1. Double-contrast air study of colon demonstrating two smooth, rounded polyps involving the sigmoid flexure.

from the adjacent joints. There was some deformity of the ends of the bones with widening but there was no evidence of shortening (figs. 2 and 3). An osteochondroma protruding laterally from the neural arches of L-4 and L-5 and a small sessile exostosis involving the lateral margin of the right ilium were seen (fig. 4). The roentgenologic findings were characteristic of hereditary multiple cartilaginous exostoses.

At operation, the colon was palpated and no polyps could be felt except those in the sigmoid colon. One polyp was excised and a second was fulgurated with coagulating current. The patient's postoperative course was uneventful. The pathologic report was adenomatous polyp, benign.

DISCUSSION

Plenk and Gardner described the hereditary pattern of osteomatosis (leontiasis ossea) associated with polyposis of the colon. Four of six of their patients had cranial or facial bone osteomas plus cortical changes in the long bones. The authors noted that the associated changes in the long bones were unusual and interesting. These tumors, however, consisted of solid bone and lacked

Figure 2. Multiple cartilaginous exostoses involving the distal ends of the femur and proximal ends of the tibia and fibula.

"areas of cartilage." They concluded that, in their cases, the changes in the long bones were confined to periosteal bone formation and that "a disturbance of membranous bone formation" is the causative basis of the disease. The authors cite Billings and Ringertz,² who reported a patient with tumor of a rib, and Reiss,³ who mentioned the femur as being involved in three patients and the fibula in one.

In our patient the changes involving the long bones and spine presented the typical characteristic findings of hereditary, benign, multiple cartilaginous exostoses. Radiographically, the osteochondromatous tumors presented the classical bone projections with rarefied cartilaginous tips. There was no evidence of leontiasis ossea or of cranial, facial, or rib involvement. Two benign polyps were surgically removed, one of which was studied by the

Figure 3. Multiple cartilaginous exostoses involving the distal ends of the radius and ulna.

pathologist. On palpation the surgeon was unable to locate any other polypoid lesion in the colon, and the routine barium enema and double-contrast air examination failed to demonstrate any other lesion in the colon.

Multiple cartilaginous exostoses is known as a congenital and hereditary disease which involves bones ossified in cartilage and which, as a result of defective modeling of the bone, results in osseous deformities with exostoses.

The development of polyposis of the colon is based on a familial predisposition to this disease. The polypoid lesions may be found in early childhood but frequently are not diagnosed until later life. In view of the absence of any underlying inflammatory disease of the large bowel, the polyp formation in this patient is considered as being of hereditary origin.

Figure 4. An osteochondroma involving the neural arches of L-4 and L-5 is clearly demonstrated.

SUMMARY

A case of hereditary multiple cartilaginous exostoses associated with polyposis of the colon is reported. No identical case description could be found in the available literature.

The pathologic condition most similar is that of osteomatosis (leontiasis ossea) with polyposis of the colon. The latter disease has a hereditary pattern. The genealogy of the patient was not investigated.

Clinicopathologic Conference

Brooke Army Hospital, Brooke Army Medical Center,
Fort Sam Houston, Tex.*

ANURIA

Summary of Clinical History. This 33-year-old white male of Latin-American extraction was admitted to the hospital 18 April 1952 with the chief complaints of anuria and Hansen's disease.

The patient was well until 5 April. At that time he had a temperature of 101° F, which continued for three days. He then developed diarrhea and abdominal cramps which lasted until 12 April, when he felt well but weak. On 13 April he developed hiccoughs. Two or three days prior to the onset of the present illness the patient had consumed several beers. He also told his wife that for three weeks prior to onset he had been cleaning motors at work with a "gas" which he thought was carbon tetrachloride. He further stated that several of his fellow workers "felt sick."

The patient was an electrician. He had had military service in North Africa and Italy during World War II, and was discharged in 1944. He used alcohol occasionally and did not use tobacco. He had been given diasone (brand of sulfoxone sodium) therapy at Carville, La., until 1947 and intermittently after that by a local physician. His last medication had been in the preceding December. His father died of heart disease; his mother, two siblings, wife, and child were living and well. There was no other history of familial diseases. The patient had a slight shrapnel wound on the leg in World War II, and had had no operations. He had had the usual childhood diseases, and pneumonia in 1944. Hansen's disease was diagnosed in 1943. He was discharged from Carville in 1947 as an arrested case.

Review of systems was negative except for the genito-urinary system. The patient had had a "mild kidney disease" of unknown type in 1946 while at Carville. Several months prior to the pres-

*Brig. Gen. Stuart G. Smith, MC, USA, Commanding General. From the Laboratory Service, Col. Carl J. Lind, MC, USA, Chief.

ent illness he had noted a sharp, "knife-like" intermittent pain in his right side. He also noted swelling of feet, nausea, vomiting, and a bad taste in his mouth. His urine showed pus and blood. He was treated with penicillin and the symptoms subsided.

Physical Examination. The patient was a well-developed, well-nourished Latin American appearing acutely ill, slow in speech, and confused in thought. He was 5 feet 10 inches in height; his weight was 185 pounds average, 208 pounds maximum, and 189 pounds at the time of examination. His pulse was 108, respirations, 26; temperature, 99.8° F; and blood pressure, 142/88 mm Hg. Head, neck, eyes, ears, teeth, and throat were negative. His tongue was dry and hard, and there was a uriferous odor to his breath. Chest expansion was equal and normal bilaterally. The lungs were clear to auscultation and percussion, and the heart was entirely normal. There were no masses or tenderness in the abdomen, and no hernias. The genitalia were those of a normal adult male, and the rectum and prostate were normal. There was definite bilateral costovertebral-angle tenderness. Examination of the extremities was negative. The nervous system was normal except for a clouded sensorium. There were areas of raised macular lesions over the skin of the chest, abdomen, and flanks. A slight icterus was also noted. The lymphatic system was normal.

Course in Hospital. The patient was catheterized on the day of admission and 5 ml of dark urine were obtained. On 19 April scrapings of skin lesions of the chest were positive for acid-fast bacilli. The patient was dialyzed in an artificial kidney for 6 hours and 15 minutes on 20 April. On 22 April his general condition was improved and sensorium cleared. A biopsy of the liver (by needle puncture) was done and reported as follows: "This presents a rather unusual picture. There is marked pleomorphism of liver cells suggesting a remarkable degree of regeneration. The appearance is not typical for either toxic or viral hepatitis. There is, in addition, a considerable degree of arteriosclerosis and we wonder whether the patient has hypertension." On 30 April the patient was running a 99-100° F temperature, but otherwise was feeling well. A biopsy of the skin was reported as showing Hansen's disease. The following day the urine showed many bacteria. Temperature was responding to penicillin, and the patient was quite alert. By 9 May, however, the patient was running daily fevers. The skin showed exacerbations of lepromatous lesions. Tender nodes were noted in the right groin. Fluids were forced in an attempt to bring down the blood urea nitrogen and the nonprotein nitrogen. By 26 May, the temperature was 102° F, and there were marked exacerbations of skin lesions. The patient was running a spiking temperature on 28 May. No foci of infection were found. The sensorium was

cloudy and movements were sluggish. On 6 June his condition was the same. Dependent edema was noted. The next day the patient had an urticarial reaction to a blood transfusion. The reactions responded to Benadryl (brand of diphenhydramine hydrochloride). On 9 June the urinary output dropped below 500 ml. Temperature, however, was normal, and the skin lesions were less noticeable. On 12 June the patient was drowsy and sluggish. Output was zero. On 18 June the patient was running a rapid downhill course. Dependent edema was increasing. He was extremely weak and lethargic on 20 June and experienced two severe Jacksonian convulsions. On 21 June he was dialyzed in an artificial kidney for 8 hours and 15 minutes. The following day his general condition was the same, and on 23 June his mental condition was less confused. The urinary output was scanty. On 24 June he had several severe convulsions. On 29 June his convulsions were poorly controlled by sedation, and he died on 7 July, 80 days after admission to the hospital.

Laboratory Studies. Electrocardiograms on 18, 19, 21, 22, and 23 April showed normal tracings. On 26 April there was a borderline tracing. The pattern was not diagnostic, but was compatible with electrolyte imbalance. On 29 April and 1 May the pattern was the same. Tracings of 16 and 19 May were normal. On 13 June the tracing was abnormal, with prolonged Q-T interval, T-wave changes, and low voltage suggestive of hypokalemia. Tracing of 20 June showed slight regressive changes from that of 13 June.

On 11 June a blood smear showed marked hyperchromia, marked anisocytosis, and slight poikilocytosis. On 19 April the serum bilirubin was 0.8 mg per 100 ml; total protein, 4.1 (albumin 3.1, globulin 1.0) grams per 100 ml. On 22 April the serum bilirubin was 0.4 mg per 100 ml; total protein, 4.2 (albumin 2.0, globulin 2.2) grams per 100 ml. The thymol turbidity was 1.25; cephalin-cholesterol flocculation was negative. Total cholesterol was 281 mg per 100 ml on 12 June.

Urinalyses consistently showed 2 to 3 plus albumin; the sugar was negative. Microscopically, there were 10 to 20 white blood cells and 5 to 20 red blood cells per high power field. Occasional bacteria were noted. On two occasions the urine was grossly bloody.

The hematologic findings and excretion and electrolyte studies made during the period of hospitalization are summarized in tables 1 through 3.

Investigation by authorities at the patient's place of employment revealed that the cleaning material used was trichloroethylene, in the cold state. The cleaning operations were conducted in essentially open space. Halide detection tests indi-

cated that the concentration of trichloroethylene vapors in the atmosphere directly over the cleaning tank was less than 50 p. p. m. No concentration of the vapor could be detected in the working area immediately adjacent to the vat. Thirty other workers had been engaged in similar operations for months with no toxic manifestations.

DISCUSSION

Doctor Hayman:* It is a very great pleasure to be here, as it is to go to any Army hospital. You always learn more than you teach, I think. I was made an expert in tropical medicine by order of the Surgeon General, but not on the basis of any previous training. Unfortunately for this afternoon's discussion, there were not very many cases of leprosy in the American Army, at least not that I came in contact with.

This man was 33 years old. He was admitted in April with a diagnosis of anuria and Hansen's disease. He had been discharged from the Army with a diagnosis of leprosy in 1944; he had been treated at Carville intermittently with diasone, and had been discharged as an arrested case. He apparently got along quite well until between 5 and 8 April when he had some kind of febrile illness with a few days of diarrhea and abdominal cramps, followed by some further malaise. That was about all until admission to the hospital. Further history I take it was developed on further questioning after admission because of urinary tract disease and anuria. On admission his general physical

*Joseph M. Hayman, Jr., M. D., Professor of Medicine, Western Reserve University School of Medicine, Cleveland, Ohio.

examination was essentially negative except for areas of raised macular lesions over the skin of the chest, abdomen, and flanks, and a slight icterus. The maculopapular lesions were regarded, I take it, as characteristic of nodular leprosy. He was catheterized on the day of admission and 5 ml of dark urine was obtained. The diagnosis of Hansen's disease was confirmed by scrapings. Further study of the biopsy of the liver was done, which was reported as showing a rather unusual picture with pleomorphism of liver cells suggesting a remarkable degree of regeneration. The biopsy findings apparently had the pathologist confused because he said they were not typical for either toxic or viral hepatitis, that there was a certain degree of arteriosclerosis, and he suggested that the patient might have hypertension; this, however, had not been brought out by his physical examination, his blood pressure being 142/68 mm Hg. Furthermore, examinations of the urine showed the constant presence of albumin and a low total volume, and blood studies showed a marked degree of nitrogen retention.

Let us look at the electrolytes. Compare the values given on 18 and 19 April with the predialysis figures on the 20th. The chlorides came down and the carbon dioxide came down too. In other words, he was a little bit worse. Well, the sum of the cations and anions have to be equal, do they not? And usually when you add sodium and potassium, which make up the bulk of the cations, together, and then add the chlorides and carbon dioxide, which are the most important of the anions, your sum of chloride and carbon dioxide is 20 meq or so less than the cations because you do not determine sulfates and phosphates, and base them on the proteins. The thing that impressed me in reading this protocol is the results of the first two days, 18 and 19 April. The sum of the cations is about 124 meq, and the sum of the anions that are given is 146. Well, when you are leaving out sulfates and phosphates you cannot possibly have enough calcium and magnesium to make up the difference, so some of those figures are bound to be wrong. That just cannot be. Now the analysis that is reported on 20 April (116 for sodium and 4.8 potassium, a total cation given us of 120.8 and 89 for total anion) is much more reasonable. The difference there could well be made up in anions by basebound proteins plus sulfates and phosphates. In other words, just because you are handed out a whole flock of laboratory figures does not necessarily mean you have to accept them. You have to scrutinize them a little carefully and see if they are reasonable.

You all know the effects of dialysis on the kidney, and I do not think we need to spend time on that. The patient responded beautifully to the first dialysis with a drop in his blood urea nitrogen to approximately one quarter of what it was, and then a gradual increase until 21 June when he was again in uremia and was dialyzed again.

As far as his leprosy goes, he had been treated at Carville with diasone. Do you know what kind of a compound diasone is? It was

introduced first for use in tuberculosis and was not very good. Then it was used in the treatment of leprosy with a fair amount of success. It falls into the group of sulfonamides. We have no information as to where this man got his leprosy, but it was some years before he got into the Army. During this acute illness and his stay in the hospital with uremia, he had a recrudescence of his leprosy lesions. That is very common in leprosy; it is spoken of as a lepra reaction and occurs both in the tuberculoid and lepromatous types. It interested me that it could recur in a man, discharged from Carville as arrested, when he gets some complicating febrile illness. Now, when this man was admitted he gave a history of having drunk some beer a few days before his febrile illness, which would raise the question of whether he had toxic nephritis, or so-called lower nephron nephrosis from some contamination of the beer he had drunk. He also gave the history of having worked for three weeks cleaning motors with a gas which he thought was carbon tetrachloride. Further investigation showed that it was not carbon tetrachloride but trichloroethylene. The question is: Was his anuria and his azotemia due either to poisoning from some chemical solvent used in cleaning these motors or to some contamination of the beer he had drunk? The picture he presented on admission of a man in reasonably good shape with a normal blood pressure, a marked oliguria, and uremia would be consistent with a tubular poisoning and could have been due to either carbon tetrachloride or some other poisoning. But there are a couple of points that may exclude that, at least tentatively.

Is there anything in the history of this man's initial illness on 5 April—with a temperature of 101° F for three days, diarrhea, abdominal cramps, and then a feeling of weakness and hiccough—that would make you think that his subsequent renal lesion was not due to poisoning by chemicals? The majority of victims of carbon tetrachloride poisoning come in afebrile. The fact that onset in this man was with fever and diarrhea that subsided in one day and then with other symptoms that subsided spontaneously made me feel that his renal lesion was probably not due to poisoning.

Now, if we go back into his history a little bit further as it is given in the protocol, we find that he had some kind of kidney disease at Carville in 1946 which apparently he got over spontaneously, and that he had a type of pain in his right side with pus and blood in his urine in 1951 for which he was given penicillin and from which he recovered.

Then in 1952 we have this acute onset of fever, transient diarrhea, hiccoughs, and rapidly developing uremia. We know the man had leprosy. It seems to me the question to be decided is whether or not his anuria and his death were due to a renal lesion which was a complication of his leprosy, or whether the renal lesion which killed him was entirely unrelated to his leprosy. Nephritis is mentioned as a complication of untreated leprosy. It is stated that many persons with

leprosy die of nephritis, but in no place could I find any description of what the renal lesion was.

It seems perfectly reasonable, however, that in a chronic infectious disease such as leprosy a certain number of people might develop amyloid and might develop renal amyloidosis and die of renal insufficiency as a result of amyloid deposits in their kidneys. If this man's leprosy was pretty well arrested—I do not think we can assume it was completely arrested or he would not have had this reaction during his hospital stay—but if we assume that it was fairly well arrested, I would not expect him to go along and develop progressive amyloid disease. Moreover, amyloid disease, as far as I know, would not account for the three bouts of kidney involvement—the one in 1946 while he was in Carville, this one in 1951 that from the description sounds like either glomerulonephritis or pyelonephritis, and finally this terminal bout. He had no hypertension, so that rules out arteriolar nephrosclerosis as a cause of chronic kidney disease. The intermittence of his attacks, the severity of them when they did occur, and the absence of hypertension I think make a chronic glomerulonephritis extremely unlikely. That leaves us with the question of a chronic recurrent pyelonephritis as a possible explanation. Certainly the second attack in 1951 is reasonably characteristic of a type of pyelonephritis, either with or without stone; and the onset of this final attack with fever and cramping abdominal pain, plus or minus diarrhea, is not inconsistent with an acute bout of pyelonephritis.

There is one thing which is lacking in the protocol which I would like very much to know. That is, I could find no mention of the specific gravity of the urine at any point. His urine volumes were zero, then 150 ml, and then there were three days of anuria. Then his urine volume increased up to a normal range of 2,000 ml or more, and for some time he apparently was holding his own because about that time his blood nitrogen was not increasing. That is consistent with tubular damage and he should have had a low specific gravity. Then for some reason or other, when he apparently was getting along pretty well, it seems that he became oliguric again and again, and ended up with what approximated anuria. It is rare in tubular damage to have a person begin to recover, get their urine volume up to 2,000 ml, and then relapse, but it does occur. Tubular damage can occur in chronic pyelonephritis, particularly if there has been any obstructive lesion of the ureters and the prostate. Tubular damage from obstruction is reversible, and recovery may occur.

There is another point in the laboratory protocol that may be worth commenting on. The urea and creatinine clearances are extremely low. As you see at the top of the column the normal urea clearance is about 80 ml per minute and the creatinine about 120, yet his creatinine clearance was down to 2.5 ml with a urine volume of 2,000 ml. Two thousand ml would be about 0.6 ml per minute, and if his clearance was only 2.5 ml it would mean that about 25 per cent or more of the volume of

glomerular filtrate appears in the urine, which is unbelievably high. Normally, you know, the urine volume is only 1 or 2 per cent of the volume of glomerular filtrate. I question the value of any clearances which are down in the range of under 10 ml. I think all you can say is that his clearances were very low.

In my opinion this man had leprosy, mostly the lepromatous type, and according to the record showed some recent exacerbation of his lesions. He also had an extensive renal lesion which may be amyloid, but I am more inclined to think it will show chronic pyelonephritis. Whether any obstructive lesion will be demonstrated or not, I do not know.

Dr. Hayman's diagnoses:

1. Hansen's disease, lepromatous type
2. Chronic pyelonephritis, possible amyloidosis

PATHOLOGIC FINDINGS

Doctor Kellenberger:* Concerning the possibility that this man had trichloroethylene poisoning, I think he may well have had, considering the sick feeling which he and the other men at work experienced. Preparations of the drug used therapeutically seldom have toxic effects. However, commercial products are known to cause side effects. Hamilton¹ has reviewed this subject, and fatalities are encountered. Central nervous system symptoms and gastrointestinal symptoms are most commonly encountered. The difference between therapeutic and commercial products seems to be in either intrinsic impurities or dissolved hydrocarbons. Only occasionally cases of jaundice and hepatitis are reported, and these are probably reactions to impurities.

At autopsy the skin presented only a few whitish areas on the chest. Sections through these showed a lepromatous type of leprosy.

The liver was enlarged, weighing 2,500 grams, and appeared congested. Microscopically, it showed severe congestion and the small arteries showed amyloid deposits, which in retrospect represented the same findings that were erroneously interpreted as sclerosis consistent with hypertension (fig. 1).

The spleen weighed 350 grams and grossly had the appearance of congestion. Microscopically it showed congestion and amyloid deposits throughout the red pulp.

The prostate contained an abscess 1.5 cm in diameter that appeared microscopically to be of an acute bacterial nature.

One testicle was normal but the other on cut section presented patchy areas of fibrosis. Microscopically, the section showed only a patchy fibrosis and atrophy without evidence of leprosy or amyloidosis. Grabstald and Swan² have recently reviewed the subject of tes-

*Capt. Robert E. Kellenberger, MC, USA, Laboratory Service.

ticular atrophy in leprosy and believe that atrophy is the final result of acute leprous orchitis.

Figure 1. Section of portal area of liver with amyloid in wall of small artery. This finding had been thought on biopsy to be evidence of hypertension. (Hematoxylin and eosin stain, $\times 475$)

The kidneys each weighed 200 grams and were slightly larger than normal. The capsules stripped with ease, leaving smooth, mottled yellow-red cortices. Cut sections revealed loss of normal architecture with indistinctness of the corticomedullary borders. Throughout the cut sections there were large, poorly defined yellow-tan areas firm in consistency and waxy in appearance. Microscopic examination (fig. 2) showed almost complete replacement of the glomeruli by a homogeneous, acellular substance which took both Congo red and crystal violet stains positive for amyloid. There were numerous vessels and tubules which likewise showed amyloid deposits. The kidneys did not show inflammation.

Microscopic examination of the gastrointestinal tract disclosed amyloid deposits in the basement membranes of the mucosal glands. The thyroid presented marked interstitial amyloid deposits, as did the adrenal. The small arteries of the pancreas contained mural deposits of amyloid. There was no amyloid noted in the heart, lungs, lymph nodes, or tongue. Gingival tissue was not removed at autopsy.

Amyloidosis is a fairly common complication of leprosy. Strong³ reviewed a report from the Philippine Islands in which 16 per cent

Figure 2. Section of kidney, showing replacement of glomeruli with amyloid. (Hematoxylin and eosin stain, $\times 105$)

of the patients died of nephritis that in most cases was amyloidosis rather than true inflammation.

Pathologic diagnosis:

Renal insufficiency due to amyloidosis secondary
to leprosy

Doctor Hayman: I think this was a most interesting demonstration. The deduction made from this side of the room that sulfonamide or diasone poisoning might have been responsible for the patient's initial lesion I think was a good one, and one which I thought about for a while. But he had had his last dose of diasone somewhere back in 1947 and no symptoms until 1952. That is too long. Certainly the gross appearance of the kidney would indicate immediately that these kidneys were not the site of a chronic recurrent pyelonephritis. The histologic picture of the extensive amyloid disease I think means that he might have had a slowly progressive renal insufficiency over a long period of time, and the acute episode on 5 April probably had nothing particularly to do with his developing uremia but was simply some intercurrent infection of some kind, making diagnosis more dif-

ficult. It was an example, I think, of how long a man can go gradually developing uremia without any symptoms, because to have gotten his degree of uremia from a glomerular lesion or reduction of nephrons it must have been going on for months rather than days, as you get uremia from a tubular lesion.

I have certainly learned something and I am very much indebted to you.

Doctor Lind: I might add one last paragraph. We have a letter from Doctor R. R. Wolcott who was director at that time of the Public Health Service Hospital at Carville and he says, "Experience here does not indicate that the sulfone drugs cause kidney damage. This is not the ordinary sulfa drug, it is a sulfone. Most of the renal impairment adjudged clinically and at the autopsy table was a part of widespread amyloidosis which often complicates a long-standing leprosy infection. Necrosis caused by amyloid disease is one of the leading causes of death in patients with leprosy."

NO ANATOMIC CAUSE OF DEATH

Autopsies which do not reveal a plain cause for death or in which there are trivial, equivocal or even no positive findings are a source of perplexity to the pathologist who earnestly seeks to establish a real reason for death. Mild degrees of natural disease may be present as the only finding. Meticulous elimination of other possibilities is essential before death can be ascribed to such natural disease. Changes which are the result of the dying process must be fully screened and evaluated lest they be assigned a causative role. Behind every unexpected death lurk innumerable possibilities which may escape detection unless a painstaking and thorough search is made. The task may be of Gordian complexity, but it is not to be solved by intuition or a few strokes of the knife.

—LESTER ADELSON, M. D.
in *Connecticut State Medical Journal*
p. 733, Sept. 1954

A MESSAGE FROM THE A. M. A.

It is found not infrequently that physicians in civilian practice are not conversant with the varied activities and services offered by the American Medical Association. What is the American Medical Association—Why does it exist—How is it organized—How does it function—How are its policy positions determined on national matters which affect the medical profession—What does it offer to physicians and the public?

Physician members of the Association should know the answers to these and similar questions concerning their organization. It is important to realize that the average practicing physician is the local representative of the American Medical Association to his patients, his friends, business associates, and his community. He is the A. M. A. to them.

A number of physicians, when called into active service with the Armed Forces, desire more information about their association and show more interest in its activities. For these reasons, this and subsequent articles to appear in the *U. S. Armed Forces Medical Journal* will be devoted to exploring the American Medical Association; its organization, function, history, and purpose.

The American Medical Association was founded on 5 May 1847, when 250 delegates representing more than 40 medical societies and 28 colleges, embracing medical institutions in 22 states and in the District of Columbia, met in the hall of the Academy of National Sciences in Philadelphia, Pa. Its first president was Dr. Nathaniel Chapman of Pennsylvania. In the past century, the American Medical Association has grown from an organization of a few thousand to a membership of more than 155,000 physicians of 1,911 component county and district medical societies and 53 constituent state and territorial medical associations. Its influence has expanded from that of a medical debating society to a world leader in medicine and a respected voice in American affairs.

The Association has as its objective the promotion of the science and art of medicine and the betterment of public health. It is a physicians' organization existing to serve the physician and the general public.

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.
—Editor.

Each component county medical society, on the basis of provisions set forth in the constitution and bylaws of its respective state, selects delegates to represent that county in the House of Delegates of the state medical association. In turn, each state and territorial medical association selects one delegate per 1,000 A. M. A. members, or fraction thereof, to represent that state in the House of Delegates of the A. M. A. In addition, as provided in the bylaws, the House of Delegates includes representatives of the federal medical departments of the armed services, Veterans Administration, and the U. S. Public Health Service. The House of Delegates, composed of 192 physicians, meets semi-annually. It is the policy-making body of the Association. The House of Delegates elects seven officers and nine trustees. The Board of Trustees, the President, and the President-Elect serve as the interim governing body of the Association.

A physician may be an active, associate, service, or affiliate member of the American Medical Association. Provisions are also made for the election of honorary members.

Active membership is limited to those members of constituent associations who hold the degree of Doctor of Medicine or Bachelor of Medicine and who are active members of their constituent association with the right to vote and hold office. Service membership may be held by regular commissioned medical officers of the Army, Navy, Air Force, or U. S. Public Health Service, including reserve officers of the U. S. Public Health Service on active duty, who have been nominated by the Surgeons General of the respective services. The permanent medical officers of the Veterans Administration and the Indian Service, who have been nominated by their Chief Medical Directors, may likewise become service members. Service members retain membership as long as they are on active duty, and thereafter, if they have been retired in accordance with federal law and do not engage in active practice.

Only active and service members of the Association have the right to vote and the privilege to hold office.

Membership dues, which include a subscription to the *Journal of the American Medical Association*, are \$25 annually. Annual dues are recommended by the Board of Trustees and approved by the House of Delegates. Dues will be remitted 1 January or 1 July following the date of entrance into military service to all members temporarily in the Armed Forces and the U. S. Public Health Service, regardless of local dues exemption.

In the next and subsequent issue of the *Journal* some of the Councils, Committees, Bureaus, and Departments of the American Medical Association and their activities will be discussed.

PROMOTIONS OF OFFICERS

The following officers of the military medical services on active duty in the Army, Navy, and Air Force have recently received *permanent* promotions to the rank indicated:

Medical Corps

DEATHS

COREY, Giles Patterson, Lieutenant (MC) USNR, New Bern, N. C.; U. S. S. *Antietam* graduated in 1951 from the Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, N. C., appointed a Lieutenant (jg) 31 August 1953; ordered to active duty 30 October 1953; died 23 October 1955, age 30, at the Duke Hospital, Durham, N. C., of multiple myeloma.

HARRIS, Louis Marshall, Captain (MC) USN, Newport, R. I.; U. S. Naval Hospital, Newport; graduated in 1931 from the University of Arkansas School of Medicine, Little Rock, Ark.; commissioned a Lieutenant (jg) in 1931; died 11 November 1955, age 54, at the Newport Naval Hospital, of coronary occlusion.

OWNBY, Thomas "J," Commander (DC) USN, Brooklyn, N. Y.; U. S. S. *Wisconsin*, graduated in 1931 from the Kansas City-Western Dental College, Kansas City, Mo.; appointed a Lieutenant (jg) in the United States Naval Reserve 30 April 1942; ordered to active duty 4 August 1942; released to inactive duty in November 1945; commissioned a Lieutenant Commander in the Regular Navy in October 1948; died 18 October 1955, age 47, at his home in Brooklyn, N. Y., of coronary thrombosis.

VARELIA, Helen Louise, Ensign (MSC) USNR, Los Angeles, Calif., U. S. Naval Hospital, San Diego, Calif.; graduated in 1951 from the Fresno State College; appointed an Ensign and ordered to active duty 11 January 1955; died 3 November 1955, age 26, at the San Diego Naval Hospital, of a sub-arachnoid hemorrhage.

Reviews of Recent Books

PSYCHIATRY FOR THE FAMILY PHYSICIAN, by *C. Knight Aldrich*, M. D.
276 pages; illustrated. The Blakiston Div., McGraw-Hill Book Co., Inc.,
New York, N. Y., 1955. Price \$5.75.

This is a real gem and by far the most worthwhile of the many volumes available which explain psychiatry and its principles to the non-specialist. The scope of the book is comprehensive, its style admirably lucid, and the absence of the usual psychiatric jargon is most commendable. The author never commits the fault of being condescending or patronizing to the family physician, but instead presents his subject in the most understandable and logical manner, ending each chapter with a brief summary.

By far the best chapter is the one dealing with treatment, in which is described actual treatment methods that the family physician can use. Essentially these are brief psychotherapeutic methods, using the technics of psychologic support which the author reasonably feels is applicable to a series of treatment periods averaging only 20 minutes each.

This admirable volume is highly recommended not only for "family physicians" but for medical students as well. It is a true teaching text, and even psychiatric residents beginning training would benefit from reading it, if only to see how logically and simply the subject can be presented.—*JOHN F. MC MULLIN, Capt. (MC) USN*

ANNALS OF THE NEW YORK ACADEMY OF SCIENCES, Volume 63, Art. 1,
Pages 1-144, July 15, 1955, edited by *Roy Waldo Miner*. "The Regulation of Hunger and Appetite." Conference Chairman and Consulting Editor: *Franklin Hollander*. 143 pages; illustrated. The New York Academy of Sciences, New York, N. Y., 1955. Price \$3.

In November 1954 a conference on the regulation of hunger and appetite was held at the New York Academy of Sciences. Thirteen papers dealing with regulating mechanisms and clinical aspects were presented. These articles constitute one of the best sources of our scientific knowledge of hunger and obesity to be found anywhere. Free from the emotional bonds that grip many papers on the subject, reports of experiments and clinical observations are presented by several of the most active investigators in the field.

Some especially stimulating reports deal with a "night-eating syndrome," with special food cravings and aversions, and with a "lipostatic" hypothesis. The theme, however, is the physiologic, biochemical, and pharmacologic aspects of hunger and appetite and, therefore, is of particular interest to both clinicians and research workers. This book can be highly recommended.—*S. O. WAIFE, Lt. Comdr. (MC) USNR*

ADVANCES IN INTERNAL MEDICINE, Volume VII, edited by William Dock, M. D. and L. Snapper, M. D. 311 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1955. Price \$8.50.

This volume contains eight articles of current interest. The subjects covered are renal lithiasis, hepatic coma, pathophysiology of the pancreas, serum mucoproteins, physiology of clinical disorders of the adrenal gland, diseases of the pericardium, nephrotic syndrome, and applied physiology.

The physician can keep well informed of current advances in these reviews. Each subject has an extensive bibliography, and the subject and author indexes are excellent. For the physician desiring the latest information and bibliography on any of the above subjects, the book is recommended.

The reviews are of little practical value in regard to an understanding of their application to clinical medicine and are not intended for the general practitioner. The undergraduate student or the physician desiring the latest information on these subjects will find this book very valuable. The extensive bibliography for references alone justifies the inclusion of the book in the library of the internist.

—WALTON M. EDWARDS, Lt. Col., MC, USA

NEW AND NONOFFICIAL REMEDIES, 1955. The Council on Pharmacy and Chemistry, American Medical Association. 653 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$3.35.

The Council on Pharmacy and Chemistry of the American Medical Association has, as one of its primary goals, the encouragement of the rational practice of therapeutics. To aid in the attainment of this goal the Council annually publishes statements of drug actions and monographs on newer drugs in *New and Nonofficial Remedies*, and this book fills a need not met by the official drug control bodies.

The drug action portion of the N. N. R. for 1955 is excellently written. In contrast, the monographed articles seem to be neither *new* nor *nonofficial*. As an example, of the 15 articles accepted under the heading "Agents Used in Allergy," 11 have been included in the United States Pharmacopeia and one in the National Formulary. Under the section dealing with sympathomimetic substances are found 12 official substances and only 8 nonofficial ones.

There seem to be several noteworthy omissions of articles which are *new* and *nonofficial* from this edition. Under "Motion Sickness Remedies" N. N. R. lists one agent—dimenhydrinate USP—while a current review article on the subject cites equal or superior effectiveness for at least two other compounds. Under "Antidotes for Heavy Metal Poisoning," the 1955 N. N. R. includes only dimercaprol USP; and omits mention of the chelating agents which are admittedly effective in heavy metal poisoning. These omissions seem to point to the need for more emphasis on evaluation of new remedies by the Council.

In spite of omission of some really *new* drugs and a tendency to retain products which have become official and well known, this publication remains a reliable source book from which the medical profession may obtain a conservative, accurate statement of modern concepts of drug action, along with monographs on fairly new drugs.

—ROY L. MUNDY, *Capt.*, MSC, USA

THE PREVENTION OF DISEASE IN EVERYDAY PRACTICE, by *Isadore Givner*, M. D., F. A. C. S. and *Maurice Bruger*, M. Sc., M. D., C. M., F. A. C. P. 964 pages; illustrated. The C. V. Mosby Co., St. Louis, Mo., 1955. Price \$20.

Most diseases, particularly those of an infectious nature, with the discovery of their cause, have been brought under public health control. Many other diseases, however, such as diabetes, arthritis, cardiovascular and mental disorders, and carcinoma, still are blocking progress in preventive medicine. Any further progress in such conditions will depend more and more on the practicing physician who must be concerned not only with the prevention of these diseases but also with the prevention of their complications and the complications that might arise from operative procedures which patients with these diseases frequently require.

This volume is concerned with the present-day trend on the preventive aspects of such diseases and their complications that are observed in the everyday practice of medicine. It is written by more than 40 contributing practicing physicians, each one a specialist in a recognized field of medicine, including dentistry.

Suitable references are given at the end of each of the 37 chapters. The index, printing, and binding are excellent.

Today, with the line of distinction between preventive medicine and medical practice being erased, this book will serve a useful purpose to every practicing physician.—PATRICK I. McSHANE, *Col.*, MC, USA

THE HUMAN MACHINE, Biological Science for the Armed Services, by *Charles W. Shilling*, Captain (MC) USN. 292 pages; illustrated. United States Naval Institute, Annapolis, Md., 1955. Price \$5.

The military commander who understands the physical, emotional, and intellectual complexities of his men is a rarity. Knowing full well the limited knowledge of the human organism possessed by the majority of officers holding or aspiring to positions of command, the author has provided a valuable and timely volume for their education and guidance. It is equally applicable in civilian life where "the human machine" is the key to successful progress in industry, science, and the arts.

The three parts of this readable book contain a total of 20 chapters on the human machine's construction and operation (anatomy and physiology), preventive maintenance and repair, and use in war. The style is pleasing and the context is geared to the experiences and understanding of the lay reader. Although influenced by Dr. Shilling's long

career in the Navy, full consideration is given to all aspects of the stresses of military life. Specialized sections on oral health, first aid, marine biology, and aviation medicine have been prepared by his colleagues, particularly those at the United States Naval Academy. In conclusion, the author stoutly defends the staff medical officer: "The commanding officer is not only a more efficient, but a bigger and better naval officer if he listens to professional advice in the areas in which he obviously cannot be competent."

This book is attractively illustrated and handsomely published. It has an adequate index and a bibliography of appropriate references. The foreword is by Vice-Admiral C. Turner Joy, USN.

—ROBERT J. BENFORD, Col., USAF (MC)

SURGICAL PHYSIOLOGY OF THE ADRENAL CORTEX, by James D. Hardy, M. S. (Chem.), M. D., F. A. C. S. 191 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$5.75.

This monograph considers the physiology, experimental data, and management as well as indications for use of ACTH and cortisone in various disease states. Two chapters are particularly valuable for the practical surgeon who is seeking ready information. While of interest, the remaining chapters are not so essential, as most of the information is repeated briefly in the last chapter. The format is somewhat cumbersome and occasionally distracting in that references are individually mentioned by name throughout the text, thus breaking the chain of thought. The frequent repetition of 274 references is an enormous obstacle in such a short monograph. However, this does provide a ready bibliography for adrenocortical study.

The monograph offers an encompassing review of the adrenal cortex and would be of value to house officers in surgery who are looking for efficient, practical information on this subject.

—VICTOR C. STRATTON, Comdr. (MC) USN

CARDIOLOGY NOTEBOOK For Preliminary Instruction in Medical Curricula. Columbia University College of Physicians and Surgeons. 97 pages; illustrated. Grune & Stratton, Inc., New York, N. Y., 1955. Price \$2.50.

This unique book consists mostly of illustrations with a minimal amount of words. It is designed for medical students in their first years of clinical medicine and brings together in one small volume excellent illustrations of normal and common abnormal cardiac roentgenograms, electrocardiograms, and phonocardiograms. The posteroanterior, the left anterior oblique, and the right anterior oblique fluoroscopic views of the normal heart are illustrated. Abnormal cardiac conditions best observed in these various positions are described and shown.

Normal values of pulmonary function and cardiac hemodynamics are given, as well as the nomenclature for making a complete cardiac diagnosis including functional capacity and therapeutic classification.

All in all, this is a worthwhile book for the medical student. Interns and residents will also find it useful and worth the price. An added feature is that on almost every other page there is space for making additional notes.

The authors are to be commended for including so much material so completely in such a simplified way that it can be reviewed in an hour or so, depending on the desire of the reader.

—PATRICK I. McSHANE, Col., MC, USA

IONOGRAPHY, Electrophoresis in Stabilized Media, by *Hugh J. McDonald*, D. Sc. In collaboration with *Robert J. Lappe*, M. S., *Edward P. Marbach*, Ph. D., *Robert H. Spitzer*, M. S., and *Matthew C. Urbin*, Ph. D. 268 pages; illustrated. Year Book Publishers, Inc., Chicago, Ill., 1955. Price \$6.50.

The field discussed in this volume is one in which the current rate of expansion far exceeds the amount of information readily available to a person who wishes to employ the technics involved. The author and his collaborators have produced a text that can be readily used by beginners in the field. They describe in some detail the various types of apparatus for this method of chromatography, and discuss the methods used in all phases of ionography. The importance of mobility determinations is stressed and the methods to carry out this part of the analysis are given in extra detail. The relation between mobilities in stabilized and nonstabilized media is clearly defined and developed.

Half of the book concerns the applications of this method to biochemistry. Passing reference is given to other applications. These chapters form a good review and beginning point for the investigator who would like to use these technics. The references are more than adequate and cover the field well.—IRVING GRAY, Lt. Col., MSC, USA

AN OUTLINE OF PRESENT DAY THORACIC SURGERY, by *Robert I. Carlson*, M. D. 158 pages. Educational Publishers, Inc., St. Louis, Mo., 1954. Price \$4.25.

In a 158-page brochure the author has prepared an outline of thoracic surgery primarily for medical students, interns, and residents. Its purpose is to serve as a starting point for those interested in thoracic surgery. The discussion given in outline form of necessity is brief but well presented. Several notations are made to different concepts in therapy which afford the reader a ready index for further study. The chapter on cardiac surgery is not as complete as the others that deal with the remainder of thoracic surgical topics.

The pages of the outline are bound by plastic rings which hinder the turning of the pages and frequent use will no doubt loosen many of the pages. There are no illustrations, graphs, or diagrams. The index is well organized, and the bibliography contains many references.

—JOSEPH M. HANNER, Capt. (MC) USN

LABORATORY IDENTIFICATION OF PATHOGENIC FUNGI SIMPLIFIED, by Elizabeth L. Hazen, Ph. D., and Frank Curtis Reed, 108 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$5.50.

Considering the brevity of this monograph (108 pages, 100 photographs), much useful information is presented. The essential features of the most common dermatophytes and systemic fungi encountered in North America are presented in tabular form. The photomicrographs of the diagnostic structures and tissue phases are typical and clearly correlated to textual descriptions. The fungus diseases are discussed briefly from a clinical point of view and reference is made very briefly to the use of laboratory animals and to the specimens ordinarily submitted for examination. In the last few pages, there is appended an excellent group of selected references and a compilation of formulas of the most commonly used media with, however, no guide as to their intended use.

The somewhat fragmentary information presented regarding procedures and technics, variation and growth characteristics of the pathogens, and the use of black and white photographs (in the case of the giant colonies) limits the utility of this manual to the trained worker. In order to use this monograph in a practical manner, the beginner must possess a knowledge of the relative distribution, growth characteristics, variation, and morphology of the common saprophytic forms (about which no reference has been made herein) and some knowledge of the necessary precautions and methods of collecting and treating specimens, as well as a knowledge of technics and procedures unique to mycology.

In spite of the above limitations, a definite contribution has been made in a rather complex field. To the bacteriologist, dismayed by the present state of mycologic diagnosis and possessing the requisite knowledge set forth above, the task of identifying pathogenic fungi should become less arduous and confusing with the aid of this monograph. It will also serve admirably as an aid in teaching the elements of mycologic diagnosis to beginners when used in conjunction with the display of actual giant colonies and presentation of adequate technical descriptions.—GRANVILLE M. MOORE, Lt. Comdr. (NSC) USNR.

CLINICAL TOXICOLOGY, by Clinton H. Thienes, M. D., Ph. D., and Thomas J. Haley, Ph. D. 3d edition. 457 pages; illustrated. Lea & Febiger, Philadelphia, Pa., 1955. Price \$6.50.

The format and style of this third edition of a well-known textbook remain the same as in previous editions, but there is a moderate expansion to incorporate information on recently introduced chemicals such as the anticholinesterase insecticides and defoliative compounds. Newer improved methods of analysis for the qualitative and quantitative presence of various chemicals have been substituted, and methods for the protection of additional substances such as the synthetic estrogens and antithyroid compounds have been added.

In a brief but adequate manner the chemistry, pharmacology, pathology, symptomatology, and treatment of patients with poisoning due to common substances are discussed. Poisons are grouped according to their major mechanism of action. Where they act strongly on more than one physiologic system, they are mentioned under various appropriate headings. Closely related poisons are discussed, however, under a single heading. For the general practitioner, Chapter 29, "An Outline of Symptom Diagnosis," is of value in the differential diagnosis of various types of poisoning. The last third of the book is devoted to analytic methods for the qualitative and quantitative detection of the various poisons. The original references for most of these methods are stated, but the symptoms and treatment are covered without any bibliography other than a mention in the preface of other books of toxicology. A moderate number of pertinent illustrations accompany the methods for chemical analysis.

This book contains a large amount of information on toxicology condensed into a relatively small and useful manual. It is highly recommended as a text in a classroom or as a guide to the clinician.

—MILWARD W. BAYLISS, Col., MC, USA

MANAGEMENT OF DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM, by Louis T. Palumbo, M. D. 186 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1955. Price \$5.

In the space of less than 150 pages of text the author has attempted to cover the broad field relating to the autonomic nervous system. When one appreciates the vast anatomic, physiologic, and clinical implications of the autonomic nerves, controlling to a large extent the vitally important function of homeostasis as they do, it is at once evident this publication can but briefly touch upon the various facets of the subject.

The pattern of the book essentially follows that of other well-known works on the subject. In none of these three chapters devoted to anatomy, physiology, and pharmacology is there any new material. In the chapters covering the application of the several forms of therapy for disorders of the autonomic nervous system one gets the impression of overenthusiasm for anticipated results. There is no description of surgical technics; however, reference is made to failures to attain anticipated results because of incomplete ablation. The 172 references cover a liberal range of relatively recent literature relating to the autonomic nervous system, and the index is entirely adequate.

This volume is one of the general practice manuals and as such may perhaps serve a usual purpose, though one should not be misled into expecting miracles from the use of many of the medical or surgical procedures recommended. It is definitely not a work of reference for the specialist and does not represent any original investigation.

—EVERETT H. DICKINSON, Capt. (MC) USN

EXPERIENCING THE PATIENT'S DAY, A Manual for Psychiatric Hospital Personnel, by *Robert W. Hyde*, M. D. 214 pages. G. P. Putnam's Sons, New York, N. Y., 1955. Price \$2.20.

This book, written with the collaboration of the attendants of the Boston Psychopathic Hospital, is exactly what its subtitle says. It is the outcome of a series of group discussions that the author had on a continuing basis with his attendants, to increase their potential skills in working with patients. "The education of the attendant is primarily the process of observant participation with patients, where together they may understand the essential elements of human experience."

Various sections are entitled "The 24 Hour Day," "Examination of the Patient," "Treatment," "Symptoms and Diagnosis," "Orientation," "Problems," and "Ward Problems." Each section has an introductory note describing the subject, and then reports the interchange of thoughts and feelings of the attendants, who actually spend most time with the patients. The varying attitudes toward particular problems, toward patient behavior, et cetera, and the way they impinge on the therapeutic program, are clearly delineated.

A similar program on a much smaller scale has been instituted—with encouraging results—on the several services where this reviewer has been chief. It is therefore recommended that copies of this excellent manual be available at all military installations where neuropsychiatric staff personnel are in training.

It is regretted that the binding is of paper, because this book will be much in use. —*FELIX H. OCKO, Capt. (MC) USN*

SADDLE BLOCK ANESTHESIA, by *Ray T. Parmley*, M. D. 59 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$2.50.

Although the material presented in this short monograph is highly technical, it is written in a clear, logical style. The presentation should appeal to both the general practitioner and the obstetrician, who are called upon to perform spinal analgesia, and should be instructive to residents in anesthesia.

The anesthesiologist will find nothing new in this monograph. However, the general principles of spinal analgesia are so clearly described that even the specialist can profit from such a well-organized review. There is no doubt that the author has a wide experience with the spinal technic. The rules he sets down for successful spinal analgesia can come only from a great deal of personal experience. The unpopularity of spinal analgesia in some localities is discussed. The fear of this technic apparently lies in the medicolegal implications. There is one small complaint. The references to the figures are confusing.

SYSTEMIC LUPUS ERYTHEMATOSUS: Review of the Literature and Clinical Analysis of 138 Cases, by A. McGehee Harvey, M. D., Lawrence E. Shulman, M. D., Philip A. Tumulty, M. D., C. Lockard Conley, M. D., and Edyth H. Schoenrich, M. D. 437 pages; illustrated. The Williams & Wilkins Co., Baltimore, Md., 1955. Price \$3.

This book is a reprint of an article that appeared in the December 1954 issue of *Medicine*, and constitutes an excellent review of the clinical aspects of systemic lupus erythematosus. It is an analysis of 138 cases from the Department of Medicine of the Johns Hopkins University and Hospital and a review of the literature on this topic. The protean manifestations of the disease are stressed. The L. E. cell phenomenon is adequately discussed as well as the chronic biologic false positive serologic tests for syphilis. Of great value to the internists and rheumatologists are the 29 pages devoted to hormone therapy, outlining the specific effects of such therapy on the specific manifestations of the disease. One of the most valuable features of the book are the illustrative patients that have been carefully selected to show the protracted course of the disease, the varied symptomatology, the diagnostic problems they initially present, and the effects of hormonal therapy on the various systemic manifestations.

This book is the most complete treatise in print today on systemic lupus erythematosus. An excellent bibliography is appended, the illustrations are excellent, and the many tables and diagrams are clearly and concisely presented.

Those interested in connective tissue disease will find the book a valuable addition to their library and one they will constantly use.

—LEON J. NUMAINVILLE, Col., MC, USA

J. A. M. A. Clinical Abstracts of Diagnosis and Treatment. Published with the Approval of the Board of Trustees, American Medical Association. 627 pages. Intercontinental Medical Book Corp., with Grune & Stratton, Inc., New York, N. Y., 1955. Price \$5.50.

This is the first of an annual series of clinical abstracts culled from 1,200 periodicals, selected by Nash D. Fabricant, M. D., Editorial Associate, Journal of the American Medical Association.

The abstracts have been grouped under 14 headings: Internal Medicine, Surgery, Neurology and Psychiatry, Pediatrics, Gynecology and Obstetrics, Dermatology, Urology, Ophthalmology, Otolaryngology, Therapeutics, Pathology, Radiology, Anesthesia, and Physiology. The index is unique in that each of the above-named sections is alphabetized individually rather than collectively.

The grouping of these abstracts, while of limited value in diagnosis and treatment, permits a quick determination as to the desirability of studying the original articles. Likewise, the physician preparing a paper for presentation to a medical society or journal has a ready reference, easily located, due to the grouping of the various subjects.

—ARTHUR E. WHITE, Col., MC, USA

PROGRESS IN NEUROLOGY AND PSYCHIATRY, An Annual Review, Volume X. Edited by E. A. Spiegel, M. D., 645 pages. Grune & Stratton, Inc., New York, N. Y., 1955. Price \$10.

The purpose of this series as stated in the preface to this 10th annual volume is ". . . they bring the reader up to date regarding recent developments in the fields of neurology and psychiatry, (and) their basic foundations and clinical ramifications . . ." It is believed this purpose has been achieved in noteworthy fashion.

The current volume makes its usual significant contribution to our integrated knowledge of psychiatry and neurology. It is essentially a synthesizing effort in which the essential elements of the many papers reviewed are presented appropriately in relationship to each other and in relationship to the logical subdivisions of the already known.

The table of contents is logically and usefully devised; references are complete; and the volume is well indexed. The presentation is in narrative form, readable, and particularly valuable because of its intrinsic integrating and synthesizing qualities.

This, as are the previous nine volumes, is a record of history in the making, and should be read by all in the field who wish to keep their knowledge current. — DONALD B. PETERSON, Col., MC, USA

BRITISH MEDICAL BULLETIN, Blood Coagulation and Thrombosis, Volume XI, Number 1. 82 pages; illustrated. Published by Medical Department, The British Council, London, April 1955. Distributed by Oxford University Press, New York, N. Y., Price \$2.75.

This book is the latest in this important series of reviews. After the heavy dose of clotting-in-the-test tube which the medical world has endured these 20 years, a trend toward a wider view of hemostatic disease is long overdue and more than welcome. The coagulationists have done well in these years, uncovering a dozen clotting factors and two new hemorrhagic diseases for each factor. We have grown to think of hemostasis and coagulation as equivalents with the flaws of one inevitably reflected in the other. Through publications such as this one a better perspective is coming to focus. We are learning to appreciate that faults of the hemostatic mechanism may be insignificant, they may cause bleeding, they may permit bleeding (with injury), or they may cause thromboembolism. Of these diseases, bleeding is the most flamboyant and, perhaps, that is why it has received most attention. But thromboembolism kills more people than any other single disorder. We are doing well nowadays to single it out for attention.

The issue of this journal at hand is the best contemporary statement of our clinical and investigative positions with relation to hemostatic disease, both hemorrhagic and thrombotic.

—WILLIAM H. CROSBY, Lt. Col., MC, USA

1955 MEDICAL PROGRESS. A Review of Medical Advances During 1954, edited by *Morris Fishbein*, M. D. 346 pages. The Blakiston Div., McGraw-Hill Book Co., Inc., New York, N. Y., 1955. Price \$5.

This book undertakes to present a review of the new advances in the various specialties of medicine occurring since the 1954 edition. This purpose is adequately accomplished by 28 contributors, including many men of importance in American medicine. The majority of these contributors represent three centers of medical education: Chicago, Boston, and Rochester, Minn.

The book will find its greatest usefulness in the hands of the general practitioner of medicine, to whom it offers a moderately comprehensive report of current thought in a single edition. For this reason the book has some value for the military physician practicing in any area except a major military medical center.

Inherent in such a presentation is the difficulty in achieving a proper balance in presenting evidence of progress in the various specialties. The chapter entitled "New Drugs" merits 5 pages. "Cardiovascular Diseases" receives a scant 7 pages, including 2 pages of bibliography, while "Endocrinology" spans a full 36 pages of textual material and 4 pages of bibliography. Many cardiologists would disagree with the author's opinion that "during 1954 nothing spectacular was added to the armamentarium of the physician dealing with cardiovascular diseases."

—DAVID B. CARMICHAEL, Lt. Comdr. (MC) USN

DOCTOR AND PATIENT, by *Desmond O'Neill*, M. D., M. R. C. P. (Lond.), D. P. M. (Eng.). 197 pages. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$5.

This book was originally published in England under the title, "A Psychosomatic Approach to Medicine," which I believe to be a better title than that of this edition. Reflecting the author's extensive experience as a specialist in psychiatry, the book will be of most value to the general practitioner, but will also be interesting and helpful to the various specialists. Psychiatrists will enjoy it; their foundation in psychosomatic medicine will be strengthened, and they will benefit especially from the chapter devoted to recent experiments which throw light on physiologic responses to stress. A short chapter discusses the origin, decline, and resurgence of the concept of the whole—the total personality—the conviction that the proper object of the physician's study is the patient and not the disease. One chapter discusses, and quotes figures of, a carefully planned survey of the prevalence of stress disorders which are observed by the general practitioner and specialists. The greater portion of the book is devoted to a discussion of 22 of the more common, major symptom-complexes commonly found in stress disorders. Numerous short case reports are given as illustrations, failures as well as successes are cited, and the probable causes of failure are discussed.

The various therapies of the stress disorders are described for the general practitioner, and for specialists other than psychiatrists. A bibliography consisting of an adequate number of the best references will satisfy the vast majority of readers and is appropriate to this presentation. This small, inviting, unusually readable book is recommended for every physician.—EATON W. BENNETT, Col., MC, USA

INTESTINAL OBSTRUCTIONS, Physiological, Pathological, and Clinical Considerations with Emphasis on Therapy, Including Description of Operative Procedures, by *Owen H. Wangensteen*, M. D., Ph. D. 3d edition. 838 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$15.50.

The first new edition of this book in 15 years reflects the many years of study and experimentation in the physiology laboratory and analysis of the subject by Dr. Wangensteen and his colleagues at the University of Minnesota. The book is well written in an informal style and is printed in most legible type on excellent paper. Illustrations are in black and white and are good. The bibliography is exhaustive.

The first part of the book presents the pathologic physiology of distention, diagnostic considerations, fluid replacement therapy, intestinal intubation as a therapeutic measure, the factors leading to the decision to operate, the selection of the proper operative procedure in the individual patient, and postoperative care and mortality. The remainder of the book concerns itself with specific causes of obstruction, from the common adynamic ileus to the rare internal hernia.

Dr. Wangensteen observes good teaching practice—constant repetition of the points he considers of most importance. He is a stalwart champion of the aseptic closed type of intestinal anastomosis and believes strongly that an open type of anastomosis protected by intestinal antibiotics is an inferior procedure. His belief in this matter is not shared by a majority of surgeons, but there is no denying that, statistically, his method is good. The one-layer anastomosis is also strongly championed. There undeniably is much to recommend it.

The section devoted to the passage into the small bowel of the Grafton-Smith tube with maneuverable stylet control under fluoroscopic visualization is most interesting, as is the discussion of the use of enterostomy in intestinal obstruction.

There is no doubt that this book is no compiling of ideas from the works of other people but, rather, represents the opinions of a skilled and able surgeon and teacher based on many years of his own and his staff's experience in clinic and laboratory. Any surgeon receiving patients from outlying regions knows with what consistency intestinal obstruction can be mishandled. This book is highly recommended for the library of all physicians who may be expected to handle the life-or-death problem of intestinal obstruction.

—DAVID E. THOMAS, Lt. Col., MC, USA

CARDIAC AUSCULTATION, Including Audio-Visual Principles, by J. Scott Butterworth, M. D., Maurice R. Chassin, M. D., and Robert McGrath, M. D. 111 pages; 54 illustrations. Grune & Stratton, Inc., New York, N. Y., 1955. Price \$4.50.

This is a book devoted entirely to auscultation of the heart. The authors take up the history of auscultation, the equipment used in their particular study, and the physics of sound as it pertains to heart murmurs. They then discuss the clinical aspects of heart sounds and murmurs, going into some detail regarding different kinds of sounds, the evaluation of timing, duration, pitch, intensity, and the other factors which help in the interpretation of sounds and murmurs.

This study apparently represents a considerable amount of work over some period of time. The illustrations of heart sound tracings are unusually clear and the technic of recording must have been exceptional.

There are two major criticisms of this work. The first, which may be a personal prejudice of the reviewer, is that studies of this type should not be published expensively in hard covers. The second criticism, which again may be a personal idiosyncrasy, is that this is not the best way to teach physical diagnosis. The study of gross structural cardiac defects requires the liberal use of observation, palpation, and percussion as well as auscultation, plus a liberal assist from radiology and electrocardiography.

This book does serve well the purposes of the authors, and it is a noteworthy contribution to the cardiovascular literature. There is a place for it in every cardiac clinic and medical library.

—RALPH C. PARKER, Jr., Capt. (MC) USN

THE PLASMA PROTEINS IN PREGNANCY, A Clinical Interpretation, by Harold C. Mack, M. D. Foreword by Nicholson J. Eastman, M. D. American Lecture Series, Publication Number 252, A Monograph in American Lectures in Gynecology and Obstetrics, edited by E. C. Hamblen, B. S., M. D., F. A. C. S. 118 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$3.75.

This is a compact monograph covering a series of clinical and laboratory studies on human plasma proteins in pregnancy from the pre-conceptional state through postpartum readjustment. Use is made of the newer technic of electrophoresis for analysis and comparison of normal and pathologic changes in maternal and fetal physiology. The material presented includes the structure and functions of blood proteins, the plasma proteins in normal pregnancy, the plasma proteins in toxemia, and other disorders of pregnancy and fetal plasma proteins.

The author has attempted to correlate his findings with information he and his collaborators obtained by other methods, as well as with reports of other investigators. To this end, the literature has been extensively reviewed. The limitations of the various analytical procedures, including electrophoresis, are discussed. The author cautions against making generalizations on the basis of information presently

available, because of the multiple factors influencing protein metabolism in pregnancy. A comprehensive bibliography is appended, covering nutrition and nutritional deficiencies, electrolyte and water balance, blood, hemoglobin and plasma proteins, lipoproteins, antibody formation, sodium retention, kidney and liver function, and related subjects connected with protein metabolism in pregnancy.

This book will be of interest to practicing obstetricians generally, and of particular value for reference use by clinical investigators in the field.—*ARMAND J. PEREYRA, Capt. (MC) USN*

SEXUAL HYGIENE AND PATHOLOGY, by *John F. Olven, M. D.* 481 pages. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$10.

As its preface states, this volume is "designed to fill the needs of practicing physicians, medical students, and certain groups of ancillary medical workers," and it appears to have fulfilled this intention well. The material is organized into four parts: sexuality in childhood, sexuality in the second decade, sexuality in the normal adult, and sexual pathology. The author gathered much of his material from physicians in general practice who kept records of sexual problems about which they were consulted medically and of information that they would have found helpful at those times. Therefore, we find discussed such diverse problems as those of domestic nudity, enemas, tomboyishness, pornography, petting, contraception, artificial defloration, et cetera, in addition to the usual standard subjects of discussion. Several sections of special interest deal with advice regarding sexual activity of patients with heart disease, obesity, pregnancy, orthopedic impairment, et cetera. The extensive treatment of the subject matter is exemplified by the definitive discussion of aphrodisiacs and anaphrodisiacs.

There is a mass of material covering practically every question any patient might raise in his family physician's consulting room or which the physician might be called upon to answer because of his position in the community. The text is happily not weighted down by footnotes, statistics, charts, tables, or other paraphernalia of the scientific treatise. There is enough theoretical discussion to make it more than a mere tabulation of various sex practices, normal and abnormal, and yet not so much as to make it a textbook of psychiatry or sexology. Only in the section on sexual deviations does the author seem overly concerned with the intricacies of the psychopathology involved. Because of the attempts to comment on all possible aspects of each deviation, this section could well prove confusing to the nonpsychiatric practitioner. Altogether this is a volume regarded as particularly useful to the general practitioner, but it would not be out of place on the bookshelf of the gynecologist, urologist, internist, or psychiatrist. It may be of value as well to the public health nurse and the social worker, provided it is used with proper medical supervision.

Monthly Message

This office is particularly happy to announce this month the departure of two teams to study nutritional problems of the armed forces in Iran and Pakistan. These teams will operate under the auspices of this office through the Interdepartmental Committee on Nutrition, of which I am chairman.

A preliminary survey of the needs of these countries was made during a trip to the Near East last April by Dr. Dwight L. Wilbur, the late Dr. Harold R. Sandstead, Commander Henry T. Gannon (MC) USN, and me. A most generous and cordial reception was afforded us and full cooperation extended by the two governments involved and by our own Military Assistance Groups. Funding has been provided through the Assistant Secretary of Defense for International Security Affairs. Dr. Sandstead was to have been the leader of these groups, but due to his tragic death recently in the sabotaged airliner out of Denver, it was thought momentarily that our plans would have to be abandoned. Fortunately, however, Dr. John B. Youmans, Dean of Vanderbilt Medical School, Nashville, Tenn., has obtained leave of absence and kindly consented to accompany the teams during the first part of their stay.

It is anticipated that these surveys will require between two and three months, during which period instruction will be given to the nationals of the two countries visited. All equipment will be left with them to continue the work as they wish, and it is our aim to act in consultative capacity for them whenever they so desire. We consider this a great step forward in giving practical aid not only to the military establishments of these countries, but also to the people themselves.

Foreword

The *United States Armed Forces Medical Journal* is the medium for disseminating information of administrative and professional interest to all medical personnel of the Department of Defense. The Assistant Secretary of Defense (Health and Medical) and the Surgeons General of the several services invite all medical officers, dental officers, Medical Service Corps officers, Nurse Corps officers, and officers of the Veterinary Corps of the Armed Forces, and the medical consultants of the Army, Navy, and Air Force to submit manuscripts for publication in this journal.

FRANK B. BERRY, M. D.,
Assistant Secretary of Defense (Health and Medical)
MAJOR GENERAL SILAS B. HAYS,
Surgeon General, United States Army.
REAR ADMIRAL BARTHOLOMEW W. HOGAN,
Surgeon General, United States Navy.
MAJOR GENERAL DAN C. OGLE,
Surgeon General, United States Air Force.

ANTIMICROBIAL THERAPY OF PULMONARY TUBERCULOSIS

Current Status

PATRICK B. STOREY, *Captain, MC, USA*

JAMES A. WIER, *Colonel, MC, USA*

EFFECTIVE chemotherapy against tuberculosis in man first became available with the advent of streptomycin (SM) in 1946. In the 9 years since that time a vast amount of research has gone into the evaluation of technics of treatment with new drugs. There are still many serious problems in the treatment of pulmonary tuberculosis which await solution.

The response of tuberculous lesions of the lung to our present methods of chemotherapy seems to depend greatly on the age and morphology of the disease. Recent lesions of principally exudative character for the most part clear dramatically and more or less completely. Older lesions, associated with varying degrees of caseation necrosis, cavity formation, and fibrosis, respond less favorably and incompletely to chemotherapy. The statement may be made that the success of our present chemotherapy lies in its ability to (1) control recent exudative disease, (2) prevent further spread from caseonecrotic lesions, and (3) allow the body to proceed with its function of walling off and fibrosing the chronic nidus of infection.

Available studies from many sources to date indicate that variable chemotherapeutic regimens with presently available drugs, are very successful in achieving these objectives. Those regimens tested include daily SM with daily para-aminosalicylic acid (PAS); intermittent SM with daily PAS; intermittent SM with daily isoniazid (isonicotinic acid hydrazide, INH); daily INH with daily PAS; and intermittent SM with daily INH and PAS. Therapeutic differences among these regimens are slight, and probably depend on the pathologic type of tuberculosis under treatment. For ex-

From Fitzsimons Army Hospital, Denver, Colo. Capt. Storey is now at Veterans Administration Hospital, Baltimore, Md.

ample, patients with chronic disease with large cavities may respond more favorably to therapy with all three drugs,¹ whereas no such difference would be detected in the management of more acute, less destructive disease whether the treatment be SM-INH-PAS, SM-INH, SM-PAS, or even INH alone.

Regardless of regimen, however, two problems have not been solved: (1) the persistent cavity after treatment, and (2) the residual caseonodose lesion which almost invariably contains *Mycobacterium tuberculosis*. These may be seen readily on direct smear or tissue stain of the excised tissue. It appears, too, that with suitable technic a majority of such lesions yield organisms which can be grown.² There are as yet no extended follow-up studies to show how dangerous these caseous foci are after long-term drug therapy has been completed. Consequently, there is presently a sharp difference of opinion as to how vigorous one should be in the surgical removal of these residual lesions.

The persistent cavity poses less of a problem in the sense that the indication for surgical excision appears more clear-cut because persistent cavity with persistently positive sputum is synonymous with the eventual appearance of drug resistance of the organisms.³

It would seem then that there are two principal clinical objectives in the use of chemotherapy for pulmonary tuberculosis. The first would be cure of the disease by the use of drug therapy alone. This might be accomplished relatively readily if the lesion were of a suitable type as mentioned above, as, for example, in the patient with an early minimal lesion detected on a routine roentgenogram, or in the patient with the multiple exudative lesions of miliary tuberculosis. Or this objective of chemotherapy might be accomplished with difficulty over a long time, perhaps 2 or 3 years, in the patient with more chronic disease who for many reasons might not be suitable for surgical intervention. The second principal objective of chemotherapy would be to render the patient suitable for a necessary corrective operation, the need for which was obvious from the beginning or became apparent during treatment.

With these different objectives, drug combinations must meet different requirements, depending on the presenting clinical problem. A patient who is to have drugs for 12 months coupled with an operation to remove his focus of disease may be suitable for the very innocuous regimen of intermittent SM combined with daily INH, whereas the patient with more advanced disease involving both lungs who will require long-term chemotherapy without benefit of an operation will be a candidate for SM-PAS or INH-PAS, thus preserving sensitivity to one of the two best available drugs over a longer time.

In view of these factors, the following points may be made in the present limits of our knowledge without drawing serious objections:

1. That every patient with active pulmonary tuberculosis should receive chemotherapy.
2. That chemotherapy should be started as soon as possible, realizing that the longer a lesion exists prior to chemotherapy the less chance it has of being reversible.
3. That intermittent SM combined with daily PAS is effective treatment.
4. That, therefore, when a patient is seen with a reasonable diagnosis of pulmonary tuberculosis and after appropriate material for culture purposes has been secured, he should be started on treatment with SM-PAS to cover the period of delay that usually exists prior to his admission to a facility for the definitive treatment of his tuberculosis. This form of treatment will not be harmful and may be of considerable benefit to the patient.

Once initiated, the course of chemotherapy should be long. It is known from experience that short-term treatment, for example, from 4 to 6 months, is usually not adequate. This is known from relapse rates of treated patients, from the fact that chest roentgenograms continue to show improvement through at least 8 months of chemotherapy, and from the fact that patients who are operated on for residual lesions after 8 months or more of chemotherapy still show morphologic evidence of active disease. It is now commonly accepted, therefore, that any patient who is started on chemotherapy for tuberculosis will receive long-term treatment, of at least a year's duration. It is not presently known, although extensive current studies are in progress to try to determine, what the proper lower limit of duration of therapy is and what may be the proper upper limit.

CHEMOTHERAPY

Our presently available drugs, both well-tried and new, will be considered in the light of the previously mentioned facts. Any antituberculous drug must be considered in relation to three qualities: (1) its effectiveness against the *Myco. tuberculosis* in vitro, in the experimental animal, and in the human body; (2) the potential development of bacterial resistance to it and the clinical significance of this resistance; and (3) the clinical toxicity of the drug.

Streptomycin and INH are markedly potent agents; viomycin is moderately so, and PAS and terramycin (brand of oxytetracycline) have slight antituberculous effect. Pyrazinamide, an analogue of nicotinamide, must still be considered an experimental drug. It has some degree of effectiveness by itself, but is markedly effec-

tive in combination with INH. The newest drug available is cycloserine which is still in the early investigative phase.

Streptomycin. Streptomycin, when used alone and given daily, was found to be very effective, but this effectiveness was limited by the rapid development of organism resistance and by the high incidence of vestibular nerve damage. It was recognized that with the emergence of bacterial resistance, clinical effectiveness of the drug was lost, and deterioration of the patient ensued. Because of the vestibular toxicity, dihydrostreptomycin was introduced, and was found to be as effective therapeutically as streptomycin, and produced less vestibular damage. However, there was an alarming incidence of irreversible nerve deafness following the use of dihydrostreptomycin, and clinicians were left in the position of preferring a dizzy patient to a deaf one. Because this eighth nerve effect of the streptomycins seemed to be a function directly related to quantity used, more recently half-and-half mixtures such as *duomycin*, *combistrep*, or *distrycin* have been introduced. These preparations are still under investigation but appear to offer a solution to the problem of daily streptomycin therapy when it is indicated.

The next step in the evolution of streptomycin therapy was to give it every third day instead of daily. It was noted that the therapeutic effect of the drug was preserved, the incidence of toxicity was markedly diminished, and the incidence of bacterial resistance was reduced, but still remained about 33 per cent at 4 months (table 1).

TABLE 1. Incidence of bacterial resistance in various trials with streptomycin alone

Number of cases	Dose (grams)	Duration (days)	Percentage of patients with resistant bacteria at 120 days
100	2 daily	120	72
37	1 daily	120	67
21	1 daily	42	25
67	1 daily	28	5
28	½ daily	28	0
50	1 every third day	120	34
50	2 every third day	120	32

In a third series, 12 grams daily of PAS was added to intermittent regimen with streptomycin. The therapeutic effect was

obviously superior to that obtained with streptomycin alone and the incidence of resistance was reduced to zero at the end of 4 months.

However, the problem of PAS toxicity and patient intolerance for that drug was now added. Because of this, intermittent PAS therapy was tried in combination with intermittent streptomycin. The therapeutic response was good, but 29 per cent of those patients with positive sputum at the end of 4 months were resistant. Because this figure approximated that obtained with intermittent streptomycin alone, it was concluded that intermittent PAS therapy was not effective.

Intermittently used streptomycin combined with PAS daily was thus established as effective chemotherapy for pulmonary tuberculosis. One hundred and twenty-three patients with positive sputum and moderately advanced or far-advanced disease, were then treated for 8 months with this regimen. Of these, 94 per cent converted to persistently negative sputum cultures. Of the seven patients with positive cultures, one had organisms resistant to streptomycin (table 2).

In an extensive investigation of three SM-PAS regimens (1 gram daily SM-PAS; $\frac{1}{2}$ gram daily SM-PAS; and intermittent SM-PAS) carried out by the Veterans Administration, no significant differences in therapeutic effectiveness were observed.^{4,5} However, in studies of the British Medical Research Council it was reported that there was a definite reduction in number of *Myco. tuberculosis* resistant to INH at the end of 3 and 6 months of drug therapy when SM was given 1 gram daily rather than twice weekly in combination with 200 mg. of INH.⁶

Isoniazid. Isonicotinic acid hydrazide (isoniazid, INH) has now been under extensive laboratory and clinical investigation for 3 years. In the earliest clinical studies iproniazid (an isopropyl derivative of INH) was used more frequently than isoniazid, but because of its high incidence of toxicity it has been almost completely supplanted by isoniazid in clinical use. About half of the patients treated with iproniazid develop toxic symptoms, principally dizziness, but also many other symptoms such as muscle twitchings, blurred vision, and headaches, which will be severe enough to require discontinuation of the drug.⁷ On the other hand, in a study of 170 patients at this hospital, clinical toxicity attributable to INH has been minimal. The one serious toxic effect reported has been peripheral neuritis, which is related to the dose of INH used. At 300 mg. of INH daily, peripheral neuritis is very rare, but as the dose is increased it becomes more frequent.⁸ When high doses of INH are used the simultaneous administration of pyridoxine will prevent the occurrence of neuritis in most instances.

TABLE 2. Roentgenographic and bacteriologic evaluation of combined SM-PAS-INH therapy

Regimen	4 months				6 months			8 months		
	SM-PAS	SM-INH	SM-PAS-INH		SM-PAS	SM-INH	SM-PAS-INH	SM-PAS	SM-INH	SM-PAS-INH
Number of patients	147	122	104		146	110	98	123	93	96
Moderate or marked improvement	33%	39%	46%		58%	66%	69.4%	66%	80%	81%
Cavity no longer visible	26 of 103 or 25%	35 of 89 or 39%	29 of 71 or 40%		51 of 102 or 51%	51 of 82 or 62%	34 of 69 or 49.3%	55 of 90 or 61%	49 of 71 or 69%	40 of 62 or 64.5%
Negative sputum culture	129 (88%)	113 (93%)	97 (93%)		136 (93%)	105 (95%)	96 (98%)	116 (94%)	90 (97%)	93 (97%)
Positive sputum culture	18 (12%)	9 (7%)	7 (7%)		10 (7%)	5 (5%)	2 (2%)	7 (6%)	3 (3%)	3 (3%)
Sensitive	16	6	6		8	3	2	6	2	1
Resistant to SM	0	2	0		1	1	0	1	0	1
Resistant to INH	0	1	0		0	0	0	0	0	1
Not available	2	0	1		1	1	0	0	1	1

SM resistance defined as growth in 10 μ g/ml. of culture media.INH resistance defined as growth in 5 μ g/ml. of culture media.

INH is a bacteriostatic drug, which is effective only against mycobacteria. At least in vitro, it is no more effective in massive quantities than in small quantities. The significance of this in the treatment of persons with tuberculosis is not yet known and is currently under investigation. The drug probably works by interference with the formation of an essential metabolite. Isotopic studies with C-14 labeled INH in the culture medium show that INH-sensitive organisms absorb and fix the INH, whereas INH-resistant organisms do not. It has also been shown that, in contrast to streptomycin or PAS, INH affects intracellular as well as extracellular bacilli.⁹⁻¹¹

The therapeutic effectiveness of this drug when used alone has been gratifying, and it is believed that it possesses at least the same range of efficacy as streptomycin. However, the *Myco. tuberculosis* from the 54 per cent of the patients who had a positive sputum culture at the end of 4 months of therapy was resistant to 1 μ g. of INH per ml., and that from 33 per cent was resistant to 5 μ g. per ml.

This last fact leads immediately to one of the most important problems in the chemotherapy of tuberculosis: What is the significance of INH resistance? At first it was presumed that it had the same ominous significance as the appearance of resistance to streptomycin and ipso facto treatment with INH alone was supplanted by treatment with INH in combination with other drugs. It soon became known, however, that unlike streptomycin-resistant organisms, INH-resistant *Myco. tuberculosis* developed in vitro lost their virulence for guinea pigs. With further development of cultural technics it became apparent that this was also true of resistant mutants developed in vivo under INH therapy. This loss of virulence was then correlated with loss of catalase activity by the *Myco. tuberculosis*, and INH-resistant bacilli could be graded according to their catalase activity. It has been shown, for example, that strains resistant to 1 μ g. of INH per ml., and even to 10 μ g. per ml., that are still catalase positive, are at most only moderately attenuated for guinea pigs and will cause fatal tuberculosis after intravenous injection. On the other hand, catalase-negative resistant organisms do not produce lethal disease in the guinea pig. Quantitative studies of catalase activity related to pathogenicity for monkeys have been found to correlate in that INH-resistant, catalase-positive organisms were pathogenic and INH-resistant, catalase-negative organisms were not.¹¹ This emphasizes the important clinical proposition of producing INH-resistant, catalase-negative organisms rather than INH-resistant, catalase-positive organisms, although it has not yet been shown that such organisms have retained or lost their virulence for humans. Studies to elucidate the matter of INH resistance are currently being carried out as are other clinical studies on INH therapy alone.

The use of the combination of streptomycin intermittently and INH daily in 122 patients treated at this hospital produced additive therapeutic effects which equaled or slightly surpassed results obtained with SM-PAS therapy (table 2).

At this point a comment should be made with reference to the make-up of these series of patients. Although the patients were not selected and represent consecutive patients with positive sputum, and moderately or far advanced disease, yet they are in a sense selected by the fact that this is a military hospital. Therefore, these are for the most part young men in the prime of life with relatively recently acquired disease who have not had previous chemotherapy. If they were patients with more chronic disease, who had thick-walled cavities, or if they had had previous chemotherapy even though still streptomycin-sensitive, then we might expect a higher incidence of positive sputum cultures at the completion of 8 months of treatment. In such situations the clinical and bacteriologic studies of the U. S. Public Health Service indicate that the *Myco. tuberculosis* will become resistant to both streptomycin and INH within the relatively short period of 7 months. If these patients were not then suitable for surgical treatment this would represent a serious situation in that sensitivity would be lost to both major drugs. From the practical standpoint at this hospital the combination of SM-INH is an excellent therapeutic regimen, with very low incidence of toxicity, and will produce the desired clinical objective in almost all cases. It is recognized, however, that under other circumstances this may well not be the regimen of choice.

Because of the appearance of resistance to both major drugs when the combination of SM-INH is used, the U. S. Public Health Service has initiated studies in an attempt to find a therapeutic regimen as effective as SM-INH but one which would not result in the development of such resistance.¹⁶ This study was designed specifically to: (1) find out if there is any advantage to using an increased dose of INH (10 mg. per kg. instead of 3 mg. per kg.); (2) evaluate the regimen INH-PAS; and (3) to determine if any benefit is to be derived from the simultaneous use of all three drugs, SM-INH-PAS. At the completion of 8 months of the study, observations indicate that increasing the dose of INH increases the incidence of drug toxicity, but does not increase its therapeutic effect. The combination of INH and PAS appears to have as good a therapeutic effect as SM-INH, with the obvious advantage of not having used streptomycin. The use of all three drugs simultaneously, from the therapeutic standpoint alone, seems to offer no advantage over the other regimens.

Recently reported results from the Veterans Administration's cooperative study are interesting in this regard. In a random comparison of INH-PAS, SM-INH, and SM-PAS in the treatment of

far advanced disease, there is a significant difference in bacteriologic conversion at the end of 8 months; 65 per cent of those treated with INH-PAS having converted; 57 per cent of those with SM-INH, and 49 per cent of those with SM-PAS. With reference to triple therapy as compared with the two dual regimens of SM-INH and SM-PAS, the only significant difference appeared to be the rate of bacteriologic conversion at 8 months, which was 85 per cent for those patients treated with all three drugs as compared with 45 per cent for those receiving the dual drug regimen.¹

At this hospital a group of 96 patients had been treated with all 3 drugs for a period of 8 months. All had at least moderately advanced disease and all had positive sputum at the start of treatment. All patients were receiving treatment initially. Comparison with the previous regimens in terms of roentgenographic improvement, bacteriologic result, and the finding of *Myco. tuberculosis* in the caseonodose residual lesions on smear and tissue strain is shown in tables 1 through 3. The use of all three drugs did not appear to offer any particular advantage.¹²

TABLE 3. *Bacteriologic and pathologic findings in resected specimens from patients who received dual therapy and triple therapy*

	Dual	Triple
Positive for <i>Myco. tuberculosis</i>	69 — 93.2%	30 — 94.0%
Negative for <i>Myco. tuberculosis</i>	5 — 6.8%	2 — 6.0%
Caseonodose lesion	74 — 100%	30 — 94.0%
No caseous nodules found	0 — 0.0%	2 — 6.0%

In further consideration of the problem of INH resistance, a group of 16 patients were treated for 4 months with 300 mg. of INH daily combined with 2 grams of terramycin daily. These patients were selected on the basis of extensive disease with cavitation, so that the probability of their having positive sputum at the end of 4 months was increased. The sputum of 13 of these patients became negative by smear and culture in spite of the fact that only 2 of the 16 showed cavity closure. Of the 3 patients whose sputum remained positive, all were still sensitive to INH so that after 4 months of treatment there were no instances of INH resistance. These results, granted that the number of patients treated was small, contrast strikingly with the results of INH therapy alone for the same period of time.

Previous experience with terramycin as an antituberculosis drug had been reported from this hospital.^{13, 14} Because terramycin had been shown to have some degree of antituberculosis activity, both in vitro and in vivo, a group of 66 patients were

treated with 5 grams of terramycin daily in combination with intermittent streptomycin. The roentgenographic response was considered to be most favorable. At 4 months, sputum conversion had occurred in 77 per cent of patients. None of the positive cultures showed streptomycin resistance. Because of the mild, but troublesome gastrointestinal symptoms associated with the use of the 5-gram dose of terramycin, another group of 20 patients were given 2 grams of terramycin daily in combination with streptomycin. The therapeutic response was similar to that seen with the previous series. Sixty-five per cent of the patients obtained bacteriologic conversion. Of the seven patients who remained positive, one had developed resistance to streptomycin.

It would appear from these studies, and from others recorded in the literature,^{11,16} that terramycin in combination with streptomycin intermittently is an acceptable and useful drug regimen for the treatment of active pulmonary tuberculosis in situations where the more accepted regimens cannot be used.

Viomycin has definite but less antituberculosis activity than streptomycin and is more toxic than streptomycin. Its toxicity, particularly renal, is sufficient to preclude its daily use, but when used on an intermittent combined schedule it has its place in the chemotherapy of tuberculosis, because it is effective against streptomycin-resistant organisms.¹⁷⁻²⁰ In evaluating the therapeutic efficacy of viomycin at this hospital, it was concluded that, used alone, it did not equal the effectiveness of streptomycin alone, and in a dose of 2 grams every third day approximated the efficacy of daily PAS alone. The combination of viomycin intermittently and PAS daily was more beneficial than either alone, both from the viewpoint of therapeutic response and the development of bacterial resistance. No patient developed persistent resistance to either drug. The combination of viomycin with streptomycin intermittently appeared to be the most effective regimen, approximating the results seen previously with the SM-PAS regimen. However, one patient did develop resistance to 10 µg. of streptomycin at the end of 4 months.²¹

Pyrazinamide. More recently pyrazinamide, an analogue of nicotinamide, has come under laboratory and clinical investigation in the treatment of patients with tuberculosis. It was found to be effective in the treatment of tuberculosis in guinea pigs, with a degree of effectiveness, when used alone, somewhere between that of streptomycin and PAS. It was then shown to have a beneficial effect in persons with tuberculosis, whether or not the *Myco. tuberculosis* in the patients were streptomycin-resistant. However, the duration of good response was short-lived and it was presumed that bacterial resistance developed rapidly when the drug was used alone. Unfortunately, it was not

possible to measure the sensitivity of *Myco. tuberculosis* to pyrazinamide by in vitro technic.

Extremely interesting laboratory and clinical studies on the combined use of pyrazinamide and INH have been reported recently.²² Studies on mouse liver and spleen tuberculosis showed that this combination of drugs produced a much more eradivative effect on the disease than any other drug or combination of drugs. The clinical study by the same authors consisted of 81 patients who were treated with 50 mg. of pyrazinamide per kg. of body weight and 5 mg. of INH per kg. Of this group, 61 patients received pyrazinamide-INH for at least 3 months, with INH continued alone thereafter. Six of these patients (10 per cent) developed evidence of impairment of hepatic function; 4 of whom had jaundice and 3 of whom had severe hepatitis. Two of these last patients recovered, but one died of rapidly progressive hepatitis. Of 55 patients evaluated on the mentioned regimen, conversion of sputum on culture was accomplished and maintained in 90 per cent, substantial roentgenographic improvement occurred in 75 per cent, and cavity closure was observed in 65 per cent of those who had cavities. These results were attained in the first 6 months, with the exception of two patients whose cavity closure occurred later. There were no instances of progression of disease.

The problem of hepatic damage during clinical use of the drug is a frequent one. Of the original 43 patients treated by Yeager and associates²³ with pyrazinamide alone, 2 developed jaundice and had function tests of hepatic insufficiency. Both of these recovered. There were no other serious toxic manifestations. Campagna and associates²⁴ reported on the treatment of 21 patients with pyrazinamide-INH. Three of these patients developed mild jaundice which lasted for about a week. The liver function tests were not seriously altered in these patients, and the drug was not discontinued because the jaundice disappeared and no definite alterations in the liver function tests occurred. In a study reported by Phillips and co-workers,²⁵ 29 patients were treated with pyrazinamide. Eleven of these received pyrazinamide alone, and 18 in combination with other agents. One of the patients receiving pyrazinamide alone developed a toxic hepatitis with jaundice, which improved on discontinuation of the pyrazinamide. Of 20 other patients on whom liver function studies were done, five showed evidence of mild hepatic dysfunction as manifested by slightly elevated sulfobromophthalein retention. There were no other instances of clinical hepatitis except for the one mentioned.²⁵

Schwartz and Moyer²⁶ reported their experience at Oteen with pyrazinamide. In a 2½-year experience with 181 patients treated

with pyrazinamide, either alone or together with PAS, streptomycin, or INH, they found it necessary to discontinue treatment in only 2 patients because of mild jaundice, which appeared at 2½ months and 5 months, respectively, of pyrazinamide-INH therapy. They found pyrazinamide-INH to be a very effective regimen in the chemotherapy of pulmonary tuberculosis. It was, in their opinion, at least the equal of any combination of streptomycin, PAS, or INH. In spite of the reported toxicity, the low incidence of jaundice encountered in their series prompted them to make the recommendation that pyrazinamide-INH be used more widely in the treatment of patients with tuberculosis, particularly in streptomycin-resistant cases.

Further studies with pyrazinamide are being carried out in view of its clinical possibilities. McCune and his group¹⁷ have shown in mice that the combinations of pyrazinamide-streptomycin and pyrazinamide-PAS have shown an eradivative effect similar to pyrazinamide-INH. Morse¹⁸ at this hospital has demonstrated a fascinating correlation between degree of INH resistance and pyrazinamide sensitivity. This phenomenon has been collaborated by Middlebrook.¹⁹ A large-scale, controlled study by the U. S. Public Health Service²⁰ is under way to clarify the nature of the hepatic toxicity of the drug. The results of these studies should prove interesting as they emerge.

Cycloserine. The newest drug under investigation is cycloserine, which was reported at the 14th Conference on Chemotherapy of Tuberculosis in February 1955.²¹ It is in an early phase of clinical and laboratory investigation so that no definitive statements may be made as to its clinical place. Particularly, it does not protect mice or guinea pigs infected with virulent *Myc. tuberculosis*, even though the results reported by Epstein and associates²² indicated a definite effect in tuberculosis in humans resistant to SM and INH. Given in a dose of 1 gram daily, its most worrisome toxic effect is stimulation of the central nervous system with grand mal convulsions. The critical blood level above which this form of toxicity may occur, appears to be 50 µg. per ml.

CONCLUSIONS

For practical purposes a number of effective drug regimens are now available to treat pulmonary tuberculosis. Most patients treated at this hospital receive SM-INH intermittently, coupled with pulmonary resection when appropriate. SM-PAS or INH-PAS might be used with as good effect, but with a little higher incidence of drug toxicity or patient intolerance of the PAS. The circumstances under which it might not be elected to use SM-INH would be the presence of long-standing, far-advanced, cavitary disease in which curative surgical intervention would not be

anticipated. Here, it would probably be wise to use INH-PAS or SM-INH-PAS.

In those patients with resistant organisms who need chemotherapy, a number of alternate regimens have been suggested. The regimen to be chosen would depend upon a number of factors, especially the nature of organism resistance and drug availability.

Newer drugs are under investigation and it may be that still more effective drugs or combinations will be found in the near future.

Concepts have changed rapidly during the past few years, and they will probably continue to change, so that what may seem true now may appear quite antiquated in a short time. For example, it was proposed in the introduction that starting SM-PAS intermittently early is advantageous to the patient. This is true at present, knowing the method of treatment on which the patient will be continued to completion of his hospital care. But it may not be true next year, for it is not beyond conception that fundamental research may show that such treatment is inadequate, and inadequate treatment may allow the *Myco. tuberculosis* to adapt to its new environment.

Regardless of such speculation, however, the drugs available are powerful weapons against tuberculosis and used properly serve to reduce immeasurably the morbidity and mortality of the disease.

SURGICAL WISHFUL THINKING

The diagnosis and definitive treatment of the cancer patient is, on the whole, the most responsible function of the surgeon. Cancer is one of the only diseases the surgeon is called upon to treat which is essentially 100 percent fatal untreated. If recurrence and death from cancer were immediate and dramatic, our sense of personal responsibility would be kept taut, but the time lag in the disease allows slackening, so that too often the surgeon takes the line of least resistance from the beginning, instead of the line of *most* resistance. The serious treatment and evaluation of cancer patients is a grim business, and not too many men are willing to do the follow-up in other than a casual fashion. Personal experience is an enlightening one, and much more salutary than reading someone else's statistics. Extrapolation of results, because of comparable surgical mortality rates, into the statistical salvage rates of leading clinical centers where serious study of the disease is carried out, is surgical wishful thinking.

EFFECT OF DELAYED WARMING ON EXPERIMENTAL FROSTBITE

ROBERT B. LEWIS, *Colonel, USAF (MC)*

CARL G. HOAK, *Captain, USAF (MC)*

A NUMBER of investigators¹⁻⁷ have reported that immediate rapid thawing of frostbitten parts in experimental animals resulted in less gangrene than in controls spontaneously thawed in air.

The question arises whether rewarming must be performed immediately while the part is still frozen to obtain benefit, or if it can be delayed until after thawing has occurred.

This investigation was performed to determine the effect on the incidence and extent of cutaneous gangrene in frostbitten rabbit legs when rapid warming was delayed for various periods of time.

MATERIALS AND METHODS

The experiments were performed on 351 male albino rabbits of 2,000 to 2,500 grams body weight; 159 served as controls and 192 were treated. The animals were given a standard diet (Purina pellets) and allowed water *ad libitum* throughout the experimental periods. Freezing and thawing procedures were conducted in an air-conditioned room in which the temperature was kept constant during each experiment; the temperature varied day to day from 25° to 28°C.

Eleven separate experiments with adequate controls were performed. In five, rapid warming was delayed 30 minutes after freezing; in three the delay was 1 hour; in two, 2 hours; and in one, 4 hours.

One hind leg of each animal was prepared for freezing as follows. The hair was removed from mid thigh to foot the day before the experiments by clipping followed by the application of a depilatory cream. Immediately prior to freezing, the depilated legs were covered with a thin layer of wool fat followed with rubber condom boots. The boots were secured at the ankle with narrow strips of adhesive tape following which air was milked

From U. S. Air Force School of Aviation Medicine, Randolph Air Force Base, Tex. Col. Lewis is now assigned to Detachment 2, 7520th U. S. Air Force Hospital, Box, 64, Navy 100, FPO, New York, N. Y.

out of the boot to obviate air pockets which would alter thermal conductivity. The top of the boot was then fixed to the lower thigh by means of circularly placed adhesive tape and a pencil mark was made at the lower tip of the femur to designate the depth of immersion in the freezing bath. The freezing bath consisted of a tank of ethyl alcohol-dry ice mixture, which was kept in constant motion by means of electric stirrers. The temperature of the bath was not allowed to vary more than 0.5°C during the exposure times.

In all experiments, the exposure time was 30 minutes. The temperature varied from -15° to -18°C in different experiments to produce varying degrees of skin injury. The animals were anesthetized with Pentothal Sodium (brand of thiopental sodium) during cold exposure.

Rapid warming was accomplished by immersing the cold-injured legs in warm water at a temperature of 42°C for 5 to 8 minutes.

After warming, the injured legs were dressed with Sulfamylon ointment (brand of mafenide (4-aminoethylbenzenesulfonamide HCl)) and gauze. The dressings were changed daily until the end of the experimental periods, which varied from 6 to 9 days in different experiments. The rabbits were then sacrificed, and the incidence and extent of skin necrosis were determined. The technic for quantitative measurement of skin gangrene has been described in another article.⁶ Animals which died close to the end of the experimental periods with sharply demarcated areas of necrosis were included in the evaluations.

The statistical analysis of the results was performed as follows: For each experiment the Mann-Whitney nonparametric test was used to evaluate the difference in areas of skin necrosis between treated and control animals. From the individual P values obtained, a combined P value was computed for each specific rapid-warming delay time.

Modified "t" tests were used to determine the significance of differences in incidence of skin gangrene between treated and control animals.

RESULTS

The results are summarized in table 1. In experiments (I-V) in which rapid warming was delayed for 30 minutes, the extent and incidence of skin gangrene were significantly less than in controls spontaneously warmed in air ($P > .01$ and $P > .003$, respectively).

When the rapid warming was delayed for 1, 2, or 4 hours (experiments VI-XI), the results did not show statistically signifi-

T = treated animals; C = control animals.

*All animals were sacrificed.

•Animals which died near the end of the experimental period with well demarcated areas of necrosis were evaluated. Experiments I and VIII were performed on the same day using the same control animals.

This was true also for experiments X and XI.

cant improvement with regard to either the incidence or extent of skin necrosis when compared with controls.

In three experiments (VI, VII, and VIII) in which warming in water was delayed one hour, one showed a statistically non-significant decrease in the extent of gangrene in treated animals and in the other two the treated and control animals behaved almost identically. For all three, the combined P value was about 0.30. The P value for the difference in the incidence of gangrene between treated animals and controls for the three groups was 0.4.

Experiments in which rapid warming was delayed two hours (IX and X) gave results for which the computed combined P value for the difference in extent and incidence of gangrene was 0.2 and 0.7, respectively.

Delay of rapid warming for four hours in one experiment (XI) resulted in an incidence of gangrene of 100 per cent in both treated and control animals and the extent of gangrene was almost the same in the two groups ($P = 0.3$).

The observation that the death rate and extent of cutaneous gangrene varied considerably in different experiments, conducted under the same conditions but on different days, is not explainable but has been noted many times by the authors in past experiments with cold injury.

DISCUSSION

The results of the present investigation indicate that skin necrosis can be decreased when the rewarming procedure is delayed as long as 30 minutes. Delay of one hour or longer failed to prove beneficial in these experiments, although Entin and Baxter⁴ reported decreased gangrene after immersing frozen rats' feet in warm water following delay up to one hour after freezing. In their experiments, waiting 2 and 3 hours to rapidly warm gave results which were not better than in controls thawed in air.

It is reasonable to assume that the same results would be obtained from delayed warming of cold-injured parts in man.

Entin and Baxter found that 6 to 10 minutes were required to air-thaw rats' legs following exposure to a bath at -30°C for 12 to 30 seconds, but the original tissue temperature was not attained until 40 to 60 minutes had elapsed. In our own experience,⁵ deep leg temperatures in rabbits remained subnormal for 2 hours or longer after 30 minutes' exposure to freezing or even non-freezing cold baths.

These observations indicate that damage to tissues is produced not only during the time of solidification from cold, but that the

injurious process continues until tissue temperatures approach normal. Such a conclusion should not be surprising when one realizes that above-freezing cold can cause gangrene and less severe pathologic changes in both humans and experimental animals in so-called "trench foot" and "immersion foot or leg."

It, therefore, would seem to be of considerable practical importance not only to rapidly thaw frozen parts but also to continue the warming until the parts reach normal body temperature. Care must be taken, however, not to overheat the injured tissues, causing burn injury. Relatively mild degrees of overheating have been shown to produce tissue changes in rabbit legs.¹⁰

Furthermore, it would also seem important that rapid warming be instituted even after cold-injured parts have thawed, because one cannot always be certain that the cold intensity or exposure time or both have been sufficiently great to preclude the saving of tissue.

It is apparent that, other things being equal, the benefit obtained from rapid warming will vary indirectly with the length of time the tissue is exposed to cold, either in the cooled or frozen state.

The manner by which rapid thawing of parts frozen by relatively short exposure to cold produces improvement is not known. It would seem that the lessening of the exposure time to cold by the application of heat is the main and perhaps the entire reason for benefit.

SUMMARY AND CONCLUSIONS

In five experiments, frozen rabbit legs thawed in air at room temperature for 30 minutes, and then rapidly warmed for 5 to 8 minutes in warm water (42°C), developed significantly less gangrene than controls similarly frozen but thawed only in air. Benefit was not obtained when the rapid warming in water was delayed for 1, 2, or 4 hours after freezing. These observations indicate that damage occurs not only while the parts are frozen but also during the post-thaw period before the tissue temperatures reach normal.

OPEN TREATMENT OF BURNS

The aim in severe burns is to protect the burned area against infection, to prevent loss of fluids and absorption of toxins, and to avert loss of function and production of deformity. Treatment must be instituted promptly and burns given the same priority demanded by any serious emergency. Many investigators stress the treatment of the general condition, which is important, but it is imperative to remember that the local condition is the primary aggravating factor. It has been found that duration of illness and mortality in burn cases are considerably reduced when treatment is under unified control. There are many important advantages to the open method of treatment: greater ease of dressing than in some methods; no anesthetic necessary for dressings; debridement facilitated; constant wound evaluation, so that grafting can be done at the optimum time; active and passive motion can be started early, and drainage is promoted.

POTENTIAL REVERSIBILITY OF THE HEMIPLEGIC GAIT

WALTER J. TREANOR, *Captain, MC, USA*

RAOUL C. PSAKI, *Lieutenant Colonel, MC, USA*
ERNST DEHNE, *Lieutenant Colonel, MC, USA*

DESPITE an increased interest in the rehabilitation of patients with spastic hemiplegia, there is no objective evidence that significant improvements in technics of muscle retraining have resulted. Walshe's¹ description of spontaneous recovery to the level of an extensor leg still seems to be an adequate portrayal of the end result of present retraining methods. In obvious contrast have been the steady advances in the convalescent care of patients with paralytic poliomyelitis. It seems to us that many of the more recent improvements in poliomyelitis care have resulted from Bennett's² analytic approach. His inquiries into the dangers of precipitate ambulation and his insistence on attention to small details in therapy have contributed greatly to the reduction of deformities and to the restoration of improved functional abilities. Inherent in the Warm Springs philosophy is this emphasis on careful observation and attention to small details.

In an effort to apply some of these principles to the management of patients with spastic hemiparesis, we have followed the pattern of motor recovery in a series of 125 patients, and have observed the influence of various physical therapy procedures on this pattern. Each of these patients has been examined repeatedly throughout the cycle of recovery by one of us (WJT). This series represents a consecutive sample of patients referred to the physical medicine service of this hospital. It needs to be emphasized that this study was performed under ideal conditions, particularly in respect to the co-operation received from our colleagues in internal medicine, orthopedics, and neurosurgery.

MATERIAL

Of the 125 patients studied, 83 were males and 42 were females. In age, these patients ranged from 4 to 80 years, with a distribution spectrum as shown in table 1. It is apparent from

From Letterman Army Hospital, San Francisco, Calif. Dr. Treanor is now at St. Mary's Hospital, San Francisco, Calif.

this figure that the sample is weighted nearer the median age group than a series from a civilian hospital would be. Spastic hemiparesis occurred in 63 patients who were under 30 years of age, and from this group came a high proportion of the patients who showed maximal motor recovery.

TABLE 1. *Distribution of 125 hemiplegic patients by age and causative factors*

The causative factors productive of hemiparesis are also summarized in table 1. As is more or less inevitable, cerebrovascular accidents of unknown causation and uncertain location were numerically the most significant. However, the increasing employment of angiography as a diagnostic aid was reflected in the location of the vascular disease in 13 patients. Recovery in two of the patients with occlusion of the middle cerebral artery has already been described in detail in an article by Rosegay and Welsh.³ Angiograms revealed that thromboses adjacent to the carotid syphon were productive of hemiparesis in eight patients. That this relatively new syndrome should have been recognized so frequently in this small series of patients was due to our neurosurgical colleagues' keen awareness of the syndrome. Thrombosis at this site occurred spontaneously in seven patients and followed trauma in one other patient. Cortical damage, localized chiefly in the frontal and parietal lobes, was the result of missile entry in 12 patients and of concussion following auto-

mobile accidents in eight others. Classified as having degenerative disease were seven patients whose referral diagnosis was multiple sclerosis, and three others with the diagnosis of amyotrophic lateral sclerosis. Deliberately, we selected only those cerebral palsied children in whom the signs of an upper motor neuron deficit were confined to one side of the body. Employment of this criterion necessitated the exclusion from this report of a large number of children with spastic triplegia (in our experience, the commonest form of cerebral palsy).

From study of the levels of motor recovery which these patients achieved, we attempted to find answers to two large questions. First, we sought to define the individual components of the hemiplegic gait. Second, we sought to determine what forms of physical therapy influenced the gross appearance of this gait.

THE HEMIPLEGIC GAIT

Postural hypertonus

Expressed in Jackson's⁴ terms of a dissolution of higher functions, the hemiplegic gait can be described as "evolution not being entirely reversed, some level of evolution is left." Motor recovery occurs in a highly selective fashion, appearing earliest in the "prop muscles" of the leg, namely the extensors of the knee and ankle. Conversely, there is a relative hypotonia in the antagonistic flexors of the knee and dorsiflexors of the foot. Evidence of hyperactive postural muscle groups was found in all but 2 of the 125 patients in this series. It was seen earliest and persisted longest in those patients who were ambulated early. Clinically, it was reflected in the contrast between the patients' ability to extend the knee strongly through a wide arc of movement and their inability to flex the knee when in the prone position. There was also an obvious imbalance between strongly contracting plantar flexors and paretic dorsiflexors of the foot. Seventy-nine of these patients held the foot in a position of equinovarus, and four patients exhibited a persistent position of equinovalgus. More rapid restitution of motion in the flexor groups was seen in but two patients, both of whom had been confined to strict bed rest by reason of concomitant systemic diseases.

"Lateral leg" asynergia

A phenomenon of delayed return in the laterally placed muscles of the lower extremity was observed in the great majority of patients. As a result of this, there was gross impairment of synergic contraction of the internal rotators of the hip, of the biceps femoris, and of the muscles producing the movement of dorsiflexion in eversion (fig. 1). Restoration of this total synergy was observed in only 23 patients. It was our opinion that this dys-

synergia was a major factor in the causation of the dysmetria which was observed in almost all patients, as performance of the heel-knee test was seen to improve concurrently with correction of the imbalance between internal and external rotators of the hip. Likewise, we found that restitution of the movement of dorsiflexion in eversion was by far the most reliable indication of advanced functional return about the foot.

Figure 1. Patient with lateral leg asymmetry. There is a decrement in performance of hip internal rotation and of foot dorsiflexion on the right side.

Delayed return in proximal muscles

Persistent weakness in proximal muscle groups was seen in all patients. This phenomenon could be observed critically only in those patients who had recovered spontaneously to a considerable degree, because in more severely involved patients the obvious weakness in proximal groups could not be studied sepa-

rately from generalized weakness throughout the limb. Gross evidence of weakness in proximal muscles was seen in the persistence of a Trendelenburg limp until very late in recovery, and in the poor performance of the movement of abduction at the hip joint (fig. 2). Satisfactory volitional control of hip flexion was observed only following corrections of the imbalances between the rotator muscles and between the abductor and adductor groups. Clinically satisfactory function of the hip musculature occurred only when there was restitution of considerable voluntary power in the *gluteus medius*. A rating of normalcy was given

Figure 2. Patient with proximal paresis. Note diminished range of abduction on the right side.

when no decrement, in either range or strength, could be detected in the performance of the movements of hip abduction and of internal rotation.

Genu recurvatum

The occurrence of an apparent genu recurvatum in 47 patients could not be explained on the basis of any, or all, of the foregoing observations (fig. 3). A frequent finding in these patients with genu recurvatum was their inability to extend the leg com-

Figure 3. Patient with genu recurvatum.

pletely at the knee, especially when the hip joint had previously been placed in flexion. Likewise, they were observed to perform the movement of knee extension more slowly, and in a less rhythmical manner, on the paretic side. Incriminated in the production of genu recurvatum were paresis of the vastus medialis and the rectus femoris, and over-activity of the gastrocnemius muscles. The presence of "backknee" was usually made clinically more pronounced when patients attempted to walk on their heels. It was our experience that this deformity was persistent, and even progressive, unless preventive or corrective measures were adopted.

ALTERING THE HEMIPLEGIC GAIT

Rigid control of ambulation

Ambulation with the limb suitably splinted was encouraged throughout the stage of initial generalized hypotonia and until the extensor muscles were able to support the body weight. However, ambulation was severely curtailed throughout most of the remainder of the recovery cycle, certainly until a balance between the strength of flexor and extensor activity had been achieved. Our reasons for attempting this radical departure from usual treatment methods have been outlined in a previous report.⁵ In a special study group of 21 patients, it was very obvious to us that this policy was the most important factor in shortening the time needed for recovery of the flexor synergy. During this phase of curtailed ambulation there was no slackening in the tempo of nonweight-bearing resistance exercises directed specifically toward retraining of the flexor groups. Ambulation was permitted when it appeared that the flexor muscles had recovered sufficient strength to permit their competing successfully with the opposing extensor muscles. As a rule, this condition was satisfied when the patient could, during stance, flex the knee fully without any concomitant flexion at the hip.

Selective re-education

In keeping with the policy of reducing afferent stimuli to the postural muscles, emphasis was given to retraining of the flexor synergy. At first, painful stimuli were combined with manual resistance to reinforce the response of synergic withdrawal in all the flexors. Later, re-education exercises were prescribed for individual flexor muscles of the knee, foot, and hip joints in that sequence. Particular care was given to the restitution, by resistance exercises, of strength in the biceps femoris and the long extensors of the toes. Prior positioning of the thigh in internal rotation was also found helpful in increasing the amplitude of contraction in these muscles.

Retraining of motion about the hip was also undertaken in a selective fashion. Initially, hip abduction was reinforced by simultaneous spine extension and by traction on the leg. Insistence on bilateral contractions, performed in a prone position, obviated much of the danger arising from the performance of hip abduction by muscles extrinsic to the hip joint. The tendency of patients to perform hip flexion with the femur held in external rotation also had to be guarded against. For this reason, resistance was applied to contracting hip flexors with the femur held in a position of moderate internal rotation. Retraining of the movement of hip extension was attempted several weeks after the movements of hip flexion and abduction.

It appeared to us that the usual routine of resistance exercises for strengthening of knee extensor muscles did not materially increase the patients' ability to perform terminal extension. Because this deficit persisted until the last stages of recovery, no attempt at early correction was made. During re-education of this movement, weight-bearing was again temporarily curtailed, extension was performed in a gravity-eliminated position, and was attempted initially only through a small arc of motion. In the majority of patients, increments in range and strength occurred *pari passu* with increases in the bulk of the vastus medialis. During this phase of re-education, protection was provided for the knee joint by the application either of a long leg brace with an "offset" joint or of a "knee cage."

Chemical nerve blocks

To permit more accurate assessment of residual strength in relatively hypotonic groups, we have employed, with increasing frequency, a technic of blocking conduction in the nerve trunks supplying the stronger antagonistic extensor muscles. This procedure has been of inestimable value in determining the rehabilitation potential of individual patients, and also as a guide to the potential benefits of surgical interruption of these nerves. Because we experienced considerable difficulty in isolating peripheral nerves when using standard methods of infiltration with an anesthetic agent, an adaptation of a technic described by Sarnoff and Sarnoff⁶ was devised by one of us (RBP). A square wave pulse, whose characteristics are depicted in figure 4, was applied to the uncoated tip of an otherwise insulated hypodermic needle. Using variable voltages, it was possible to approximate the needle tip to the nerve by observation of the strength of response in the muscles supplied by the stimulated nerve. As the needle tip became more closely applied to the nerve, steadily diminishing voltages were required to produce a motor response. When a pulse of from 0.5 to 1.0 volt produced a perceptible contraction in the muscle, the local anesthetic, a 1 per cent solution of xylocaine (brand of lidocaine hydrochloride), was injected (fig. 4).

With this method of approximating the needle-tip to the nerve, as little as 5 ml. of the anesthetic agent has been sufficient for complete conduction block in even the largest peripheral nerve trunks. We were even able to confirm the fact of intraneural placement of the needle in some of the operated patients. Following complete block, a fresh assessment of the function of the previously hypotonic "unblocked" muscle group was undertaken. If increased volitional contraction was observed, we felt justified in continuing a program of muscle retraining directed specifically toward retraining this group. If, even following the

application of an adequate "reinforcing" stimulus for this group, there was no worthwhile improvement in contraction following block, we presumed that there had been long-standing "decay" of this function, and that prolonged and expensive retraining could not be justified. This technic of conduction block was also found useful as a means for determining whether extensor over-activity at either the knee or the ankle was primarily incriminated in the production of the hemiplegic gait.

Figure 4. The nerve stimulator.

Surgical interruption of nerve conduction

When a satisfactory increment in the strength of the flexor muscles was observed to follow anesthetic block of the nerve to their antagonists, the possibility of surgical neurotripty was considered. To date, a total of 29 such operations have been performed. Statistical analysis of the results of these procedures is being undertaken and will be presented in subsequent communications. Following surgical neurotripty, intensive re-education of the flexor groups (in our hands, chiefly the dorsiflexor muscles of the foot and the flexors of the knee) became easier to perform and more enduring in its benefits. Also, after reduction or elimination of the strong plantar thrust and clonus at the ankle, braces could be either dispensed with entirely or greatly reduced in

weight. Furthermore, in three patients there was a gratifying reduction in the amount of "backknee" after crushing of the tibial nerve branches to the overactive posterior calf muscles. Neurotomy, or interruption of conduction by the application of pressure to the nerve, and, in three patients, transection and immediate suturing were chosen in preference to extirpation neurectomy because of the reversibility of the block by the former means. The branches to the muscles were identified with the aid of a stimulator and were crushed at the furthest possible distance from the point of their entry into muscle (fig. 5).

Figure 5. Roentgenogram showing tantalum markers placed at site of interruption and at entrance of nerves into muscles.

We have not attempted blocking of conduction by alcohol injections because of the disadvantages of topical anesthesia produced by such blocks. Actually, surgical interruption was chosen because we were chiefly interested in the reduction of proprioceptive impulses from hyperactive muscle groups. It has

been amply illustrated that fibers carrying these impulses are as susceptible to mechanical blocking as the large diameter "motor" A fibers. The only difficulties we encountered following operation were wound infections in three patients and a too early return of function in two other patients because of insufficient pressure.

DISCUSSION

Van Buskirk⁸ recently described his observations on the mosaic of motor recovery in hemiplegia, particularly "as related to the learning of simple motor activity." The present study could be described in similar terms. Spontaneous recovery, occurring within the first 2 to 3 months following onset, accounted for most of the functional gains in our experience also. It was apparent, however, that the extent and rate of spontaneous recovery could be significantly altered by more careful control of afferent influences acting on spinal integrator systems. Limitation of standing and selective retraining of flexor activity were seen to result in an earlier restitution of the gross flexor synergy and of volitional control over individual flexor muscles. Expressed in Knowlton's⁹ terms, temporary "decay in certain existing patterns" of extensor activity was sought, in order to prevent later permanent "decay" of opposing flexion. Similarly, the practice of blocking nerves by chemical or mechanical means was designed to lessen the danger that the weaker muscle might be "ignored" in the performance of motion patterns.

This type of retraining program was based on two physiologic hypotheses. First, our observations on spontaneous recovery convinced us of the validity of Sherrington's¹⁰ concept of selective synaptic resistance. Thus, it was apparent that most afferent impulses were relayed with much greater facility to motoneurons controlling extensor muscles. In the state of increased central excitation prevailing following reduction in descending inhibitory relays, minor stimuli were seen to evoke disproportionate motor responses in these extensor groups. Conversely, it was always found difficult to produce an adequate afferent stimulus for activation of flexor motoneurons.

Second, there was ample evidence in this study of the existence of opposing half-centers in the spinal cord, that is, of an arrangement of motoneurons into antagonistic flexor and extensor groups. Following chemical conduction blocks, we observed certain alterations in strength of muscular contraction which could most readily be explained on the basis of this theory of half-centers. The decrements in quadriceps contraction which followed obturator and tibial nerve blocks led us to the conclusion that proprioceptive feed-back from the plantar flexors of the foot, from the knee extensors, and from hip adductor muscles

were all relayed to a common extensor (postural) motoneuron pool. Because the express purpose of surgical intervention was the reduction of a known amount of afferent return from these muscle groups, nerve operations were preferred to procedures on the end-organ, such as tendon lengthening.

These observations do not allow a conclusion, such as Foerster¹¹ made 40 years ago, that the factors influencing the pattern of recovery were entirely external. Neither do they support Walshe's¹² contention that the incidence of spasticity, and hence the attitude of the limbs, are determined almost completely by internal factors. It appears to us that too little attention has been paid to the control of external afferent influences, particularly those arising from receptors in antigravity muscles. The hypothesis of a potential reversibility of the hemiplegic gait is based on the alterations in performance that we have observed to result from an increased attention to the role of such afferent influences.

SUMMARY

The individual components of the hemiplegic gait have been analyzed and described under the headings of postural hypertonus, asynergia of laterally placed muscles, delayed return of proximal groups, and genu recurvatum. Among the measures suggested for improvement of the gait have been limitation of ambulation, selective retraining of flexor muscles, and chemical and mechanical blocking of the nerves supplying the extensor groups. The hypothesis of potential reversibility is based on observations made on the patterns of motor recovery in a series of 125 patients. It was supported by improvements in the extent and speed of recovery which followed closer attention to the control of proprioceptive afferent stimuli.

LACK OF JUDGMENT CAN BE LETHAL

It is a surgical truism that few patients are killed by lack of technic, whereas lack of judgment has often been lethal. Perhaps the most dangerous surgeon is the one with facility and so-called courage who lacks judgment. Today's surgical training programs are often evaluated only by the number and variety of cases done by the residents. Indications and judgments exhibited are frequently neglected. How much more revealing would be a listing of patients spared surgery after proper observation and precise etiologic diagnosis. Narrow specialized training programs in the surgical subspecialties, without the requirements of basic general surgical background, have produced many skillfully trained specialty technicians who are at a loss when confronted with general surgical problems, as they might well be in smaller communities.

THE WECHSLER-BELLEVUE SCALE IN CLINICAL DIAGNOSIS

Some Aspects of Its Use in Clinical Diagnosis

ALEXANDER TOLOR, *Second Lieutenant, USAF (MSC)*

THE PRIMARY purpose in administering any intelligence scale, obviously, is to arrive at a valid measure of an individual's level of intellectual functioning. In the past, however, as the intimate relationship existing between intelligence and personality gained increasing recognition, psychologists began to devote more attention to the manner in which various patterns on intelligence tests could be used in gaining new insights about the patient's personality. Accompanying this trend there has also been a resurgence of interest in intelligence tests with a view toward discovering the type of strengths and weaknesses which patients suffering from organic brain disease characteristically display.

One of the intelligence scales which has been found most suitable and therefore has been used most frequently for differential diagnostic purposes is the Wechsler-Bellevue Scale. This instrument lends itself readily to various types of analyses as it includes a number of verbal tests and a number of performance tests, yielding two separate quotients. Furthermore, the relationships between the scores on the various subtests can be analyzed so that any patterns, if there are such, which are characteristic of the different diagnostic groups can be ascertained.

The most obviously useful feature of the Wechsler-Bellevue Scale is its division into verbal and performance sections. There is a belief widely held among clinicians that the difference between verbal and performance sections, especially if large, is of diagnostic significance. Wechsler¹ himself contends: "... the general finding is that in most mental disorders impairment of functioning is greater in the performance than in the verbal sphere." He proceeds to explain that this conclusion applies to patients with psychosis or organic brain disease and to most psychoneurotics.

The more sophisticated methods of test analysis involve an examination of subtest scores. One commonly employed technic for differentiating between patients with cerebral lesions and

¹From U. S. Air Force Hospital, Parks Air Force Base, Calif.

those with psychoneurosis is Hewson's² pattern of deviation ratios. In applying this method, one computes a series of ratios by comparing certain of the Wechsler-Bellevue weighted subtest scores with certain others. Hewson has demonstrated on an empirical basis that these ratio scores discriminate between the two groups fairly accurately. Depending on the resulting ratios, one can conclude that the distribution resembles that frequently obtained in association with a cerebral abnormality, an emotional disturbance, or with neither of these.

PURPOSE

The present investigation had a fourfold purpose. First, I wished to ascertain whether the organic, convulsive, and psychogenic groups differed in intelligence on the full, verbal, or performance scales of the Wechsler-Bellevue. Second, it was intended to establish whether large discrepancies between ratings on verbal and performance sections on the Wechsler-Bellevue Scale discriminated among patients of the three groups. The third aim was to evaluate the usefulness of the Hewson method with these patients. Finally, I wished to determine whether the level of accuracy in making differentiations is greater when psychologic impressions are based on a whole battery of tests or when they are based only on the Wechsler-Bellevue Scale.

METHOD AND SUBJECTS

All the patients used in the present study were referred to the psychology department of Neurological Institute, Columbia-Presbyterian Medical Center, New York, N. Y. In many cases organic brain damage was suspected by the referring neuropsychiatrist, but there was often considerable doubt about the most probable diagnosis. A variety of laboratory procedures, including roentgenograms of the skull, electroencephalograms, pneumoencephalograms, et cetera, were usually performed. The psychologic tests were administered and interpreted by qualified psychologists. A typical battery of tests included the Wechsler-Bellevue Scale, Form 1, the Substitution Test, the Bender-Gestalt Test, projective drawings, and the Rorschach Test. There was considerable flexibility in choice of tests, and occasionally additional instruments such as the Thematic Apperception Test were employed.

The data with which this report concerns itself were collected independently and prior to knowledge of the patients' discharge diagnoses. The latter were made by members of the medical staff who used all the pertinent information at their disposal. It should be emphasized that the psychologists' impressions concerning the presence or absence of organicity were based solely on their observation of patients and their interpretation of test results.

Table 1 contains information pertaining to the distribution of the three groups by age, sex, and intelligence. It will be noted that there are large age and sex differences in these groups. However, since there is no reason to believe that differences in sex have any significant effect on the dependent variables, no attempt was made to equate for sex.* As for the age differences, which are in all cases significant at the 1 per cent level of confidence, the methods used in computing Wechsler-Bellevue quotients and Hewson ratios in effect make allowance for age differences.

TABLE 1. *Composition of the three groups*

	Group		
	Organic (N=91)	Convulsive (N=35)	Psychogenic (N=49)
Sex			
Male	57	14	23
Female	34	21	26
Age			
Range	12-72	12-56	12-64
Mean	44.1	27.6	35.4
S. D.*	15.1	11.9	14.2
W-B total I. Q.			
Range	54-129	61-121	79-136
Mean	90.8	94.2	110.8
S. D.	16.7	15.4	13.1

*Standard deviation

The organic group is composed of 91 patients, all having some type of intracranial abnormality. Although efforts at classification were difficult and at best unsatisfactory, the following broad and arbitrary subgroups may be distinguished:

23 with brain tumors (11 proved histologically)

16 with vascular lesions (including aneurysms, subarachnoid hemorrhages, arteriosclerotic disease, and encephalomalacia)

4 with infectious diseases (syphilis and encephalitis)

15 with head trauma (all types including surgical)

27 with degenerative diseases of the brain (including presenile dementias, multiple sclerosis, and various unspecified degenerative diseases)

*Furthermore, the composition of the groups with respect to sex is not significantly different when the organic group is compared by *t* test to the functional group or when the convulsive group is compared to the functional group. The difference between the organic and convulsive groups is, however, significant at the 5 per cent level.

6 with hereditary degenerative diseases (Huntington's chorea)

The patients falling in the class of psychogenic disorders received a variety of discharge diagnoses which often specified a particular neurosis but at times reflected the somatic concomitants affecting other systems. Of the 49 patients comprising this group, only 3 were diagnosed as being psychotic, and these were probably in partial remission. Thus, the findings cannot be generalized to psychotic patients and should more appropriately be restricted to the less severe personality disorders.

The 35 patients in the convulsive group qualified for inclusion if their seizures, irrespective of whether they were petit mal, grand mal, or psychomotor in type, were of undetermined cause. This group, therefore, refers only to patients having idiopathic seizures.

RESULTS

Inspection of table 2 reveals that the patients in the organic group differed significantly from those in the functional group with respect to mean I. Q.'s obtained on the over-all Wechsler-Bellevue Scale, on the verbal scale, and on the performance scale. The differences in each case were in favor of the psycho-

TABLE 2. Mean I. Q. and critical ratios for the groups on Wechsler-Bellevue Scales

Groups	Full scale	Verbal scale	Performance scale
Organic	90.76	92.13	92.12

**Probability

***Insignificant

genic population. The same level of significance applies to a comparison of the convulsive and psychogenic groups, the latter scoring higher on all three scales. However, there are no significant differences on any of the measures between the organic and convulsive groups.

Table 3 presents data on the per cent of cases in each of the experimental groups in which the verbal scale quotient differed or failed to differ from the performance scale quotient by at least 10 points. A chi-square test shows that the relative frequency with which the verbal I. Q. exceeded the performance I. Q. or the performance I. Q. exceeded the verbal I. Q. is not significantly different in these groups.

TABLE 3. *Relation between quotients on verbal and performance sections of the Wechsler-Bellevue Scale*

Groups	Verbal > Performance (per cent)	Performance > Verbal (per cent)	Verbal \neq Performance (per cent)
Organic	27.5	28.6	43.9
Psychogenic	18.4	26.5	55.1
Convulsive	22.9	22.9	54.2

Hewson's method correctly identified 58.2 per cent of the patients with intracranial abnormalities. It falsely suggested an organic involvement in 12.2 per cent of the psychogenic patients but correctly detected 59.2 per cent of those with a functional disorder. Only 31.4 per cent of patients diagnosed as having a convulsive disorder of undetermined cause would be considered to have organic brain disease on the basis of Hewson's pattern of deviation ratios. Table 4 summarizes the results based on this method of analyzing Wechsler-Bellevue

TABLE 4. *Hewson's pattern of deviation ratios as applied to the groups*

Group	Suggestive of cerebral lesion	Suggestive of emotional disturbance	No evidence of either
Organic (N=91)	53	32	6
Psychogenic (N=49)	6	29	14
Convulsive (N=35)	11	23	1

subtest scores. A chi-square test indicates significance at better than the .001 level.*

Table 5 shows that the accuracy of prediction is enhanced when a total battery of psychologic tests is used. A chi-square analysis indicates significance at the .001 level.

TABLE 5. *Over-all impression based on psychologic testing*

Group	Impression			
	Organicity		No organicity	
	Number	Per cent	Number	Per cent
Organic (N=91)	60	65.9	31	34.1
Psychogenic (N=49)	2	4.1	47	95.9
Convulsive (N=35)	11	31.4	24	68.6

DISCUSSION

The observation that the organic group, as a whole, scored lower on the Wechsler-Bellevue Scale than did the other patients is in general agreement with Allen¹ and with Hunt and Cofer,⁴ who found that organic brain disease tends to depress the I. Q. It is noteworthy that this lowering of I. Q. is reflected almost equally on performance and verbal tests. Contrary to the belief generally prevailing among clinicians, organic impairment does not seem to be more pronounced in the performance sphere. The assumption that emotionally disturbed patients do particularly poorly in the performance area seems likewise to be unwarranted. Irrespective of whether the mental disorder was caused by psychopathologic or organic brain disease, the majority of patients demonstrated a fairly small difference between verbal and performance section ratings. Even when this difference was large, it was probably of little diagnostic significance.

The finding that patients with demonstrable brain disease resemble more closely in intellectual functioning the patients who have seizures of undetermined cause than they do patients with psychogenic disorders is in disagreement with two studies cited by Klebanoff and associates.⁴ In these studies a similar pattern was found for epileptics and neurotics which was strikingly different from that of organic patients.

In evaluating the Hewson method for detecting organic impairment, two major limitations inherent in the methodology employed in the present study should be mentioned. Both of these operated to reduce the apparent effectiveness of her technic. The first relates to the fact that the pattern of deviation ratios should more appropriately be tested only on patients having a cerebral abnormality. No claim was ever made by Hewson that the method could be applied to any type of intracranial lesion, as was done in the present study. Second, some of the cases doubtlessly represented a mixed picture in which there were significant emotional problems present in addition to an organic involvement. In these instances the emotional problems, if severe enough, may have masked the organic pattern. Thus it would seem that her method fared rather well considering these limitations imposed by the experimental design. Omitting the convulsive patients, the Hewson method correctly identified the organic or psychogenic condition in 59 per cent of the cases. The false positives, *i. e.*, the number of psychogenic cases erroneously classified as being suggestive of organic brain disease, was restricted to 12 per cent.

It comes as little surprise that a whole battery of tests is more useful in making these discriminations than is one single test. The psychologist often obtains important diagnostic clues from instruments such as the Rorschach or the projective drawings. With the assistance of the whole battery, correct identifications increased to 76 per cent, the false positives decreased to 4 per cent. In these computations the convulsive group, which presented a special problem, is omitted. It is interesting that in only about a third of the patients with idiopathic seizures were the test results suggestive of brain disease.

SUMMARY

The present study concerned itself with the performance of three groups of patients on the Wechsler-Bellevue Scale, Form 1. Not only were intellectual differences analyzed, but the efficacy for diagnosis of various commonly employed technics based on the Wechsler-Bellevue Scale was also investigated. The subjects in this study were a group of patients with psychogenic disorders, a group of patients having intracranial abnormalities, and a group of patients having seizures of undetermined cause. The results indicated that patients with organic brain disease score lower on all three Wechsler scales than do patients with psychogenic disturbances, and that convulsive patients tend to resemble the organic subjects more closely than they do functional patients. Differences between verbal and performance scale ratings do not seem to be related to diagnostic category. It was also demonstrated that the Hewson method is helpful for

diagnosis, but that the use of a whole battery of psychological tests yields superior results.

BABIES ARE NOT STUPID

I advise my young mothers to let the baby belch after feeding, change his diaper, and place him in bed wide awake. Some state that if the baby goes to sleep while feeding, she would not dare to awaken him, but would put him down and slip out of the room. This is courting trouble. Just as the baby that is rocked to sleep requires rocking when he wakes up, so the baby that is fed to sleep demands to be fed when he awakens. He is not hungry but wants to return to the satisfactory situation he was enjoying when he went to sleep. Personally, I think he would be a little stupid if he did not expect this and it is my opinion that the average baby is far from being stupid. In fact, if we could understand them as well as they understand us, our problems would be minimal.

ROSENZWEIG PICTURE FRUSTRATION STUDY FOR SELECTING SAFE DRIVERS

FREDERICK L. MCGUIRE, *Lieutenant (junior grade) (MSC) USN*

IN CONNECTION with the problem of highway safety, recent research has concerned itself with the task of attempting to measure, by psychometric methods, those personal factors that might distinguish between the safe and unsafe automobile driver. Studies have indicated that personality-type test items show considerable promise as predictors of ability to drive a motor vehicle safely.¹⁻³

The Rosenzweig Picture Frustration Study (P-F Study), while still relatively new and untried, assumes to measure the modes of reaction to frustration that a person may adopt. The P-F Study consists of 24 picture situations involving two or more people. One person has made a statement, the other person is pictured with a blank balloon above his head. In some manner the other person is being threatened; *i. e.*, being accused of some act, being deprived of some wanted object, et cetera. The subject is required to write a reply in the blank balloon that he imagines the threatened person would make (fig. 1). In this manner, the subject's reaction to the situation is determined. The assumption is that reaction to these pseudosituations is a measure of how the subject might react in similar situations in real life. It is further assumed that the subject consciously or unconsciously identifies himself with the frustrated person in each pictured situation and projects his own bias in the replies given.

To determine this bias, scores are assigned each response as to direction of aggression and reaction type. Under direction of aggression are included (1) extrapunitive, in which aggression is turned onto the environment; (2) intropunitive, in which it is turned by the subject upon himself; and (3) impunitive, in which aggression is evaded in an attempt to gloss over the frustration. Under type of reaction fall (1) obstacle-dominance, in which the barrier occasioning the frustration stands out in the responses; (2) ego-defense, in which the ego of the subject predominates; and (3) need-persistence, in which the solution of the frustrating problem is emphasized.

From Naval Medical Field Research Laboratory, Camp Lejeune, N. C. Lt. McGuire is now assigned to U. S. Naval Hospital, Philadelphia, Pa.

From the combination of these factors there results for each picture nine possible scoring factors and two special variants.

Figure 1. Representative page from the Rosenzweig Picture Frustration Study.

It is logical to hypothesize that an automobile driver's reactions to frustrating situations, especially on the highway, could be a prime factor in determining how safely he drives. Certainly a person who is willing to accept the give and take of highway travel will not tend to commit an unsafe act when confronted by such things as traffic jams and the annoying be-

havior of certain fellow drivers. With this in mind, the P-F Study was submitted to two different groups of automobile drivers in an attempt to evaluate its ability to distinguish between the safe and the unsafe driver.

METHOD

Two groups were studied. One group consisted of those persons who had had at least one traffic accident within recent months during which they had also incurred a moving traffic violation. The other group consisted of persons who had never been involved in any kind of accident or incurred a traffic violation of any type.

The accident group was selected after an examination of Camp Lejeune accident records and was comprised of those persons who had been involved in an accident and had also been cited as being guilty of a moving violation. The nonaccident group was selected from those whose answers to a questionnaire indicated that they might be completely accident and violation free. Each of the group was further screened by interview technic.

From 446 subjects, 67 were found to be accident and violation free and to match a group of equal size from the accident-violation subjects. The basis for this selection and matching was: experience in years driving on state highways, estimated miles driven over the previous two years, age, marital status, parenthood, education in terms of highest grade completed, and number of years in service (table 1). The accident-violation record of the accident group is shown in table 2.

In addition to these factors, intelligence test scores as derived by General Classification Test (GCT) (civilian version) scores were equated on a group basis. The respective means were 108.7 and 109.2, with standard deviations (S. D.) of 17.6 and 14.8. The significance of difference between the means is represented by a critical ratio (c. r.) of 0.1947, which is not significant.

As part of a testing program each subject of both groups received the Rosenzweig Picture Frustration Study and a personal interview. The P-F Study was scored according to the method developed and outlined by Rosenzweig and associates.*

In addition to analyzing and comparing those scores routinely derived from the P-F Study, the results were subjected to an item analysis. This analysis allowed certain responses to specific test situations to be selected on the basis of whether or not they discriminated between the two groups.

RESULTS AND DISCUSSION

Of the various scores routinely produced by the P-F Study, only the Ego Defensive (E-D) and Need-Persistence (N-P) scales

showed significant differences at the 1 percent level of confidence. These results are outlined in table 3.

An item analysis of the 134 tests produced 10 significantly differentiating scores for 5 of the 24 test cartoons. These scores were all significantly different to about the 1 percent level of confidence (critical ratio as listed in table 4).

Each test was then rescored according to a method based on these 10 scores and the scores derived from the E-D and N-P percentages. The 10 items were simply arranged in order of the magnitude of the difference between the 2 groups, and the first 5 assigned a weight of 2 and the second 5 a weight of 1.

***Blame for frustration evaded

Scores characteristic of the nonaccident group were assigned a negative weight; scores characteristic of the accident group were assigned a positive weight. For those scores derived from the E-D and N-P percents, weight was given according to the number of standard deviations any particular score fell toward or away from the mean of the other group. For example, with the N-P scores, all that fell within plus 1 S. D. of the nonaccident group mean and within minus 1 S. D. of the accident group mean were given a weight of 0, because these scores overlapped to too great an extent to be helpful in distinguishing between the groups. All scores falling between 1.0 and 1.5 S. D. below the nonaccident group mean were assigned a weight of minus 1; those falling between 1.5 and 2.0 S. D. below the mean were assigned a weight of minus 2; et cetera, until all scores encountered in the study were thereby assigned a weight. All scores that fell in similar fashion about the accident group mean were assigned the same weights with a plus sign (table 5).

TABLE 5. *Weight assigned E-D and N-P percentages used in differentiating between accident and non-accident groups*

Ego-defensive		Need-persistence	
Percentage	Weight	Percentage	Weight
Under 37.0	+5	Under 11.8	-5
37.0 - 39.7	+4	11.8 - 14.2	-4
39.8 - 42.5	+3	14.3 - 16.5	-3
42.6 - 45.3	+2	16.6 - 18.9	-2
45.4 - 48.1	+1	19.0 - 21.3	-1
48.2 - 63.5	0	21.4 - 35.1	0
63.6 - 66.0	-1	35.2 - 37.8	+1
66.1 - 68.6	-2	37.9 - 40.4	+2
68.7 - 71.1	-3	40.5 - 43.0	+3
71.2 - 73.6	-4	43.1 - 45.5	+4
73.7 and over	-5	45.6 and over	+5

In order to eliminate the inconvenience of dealing with minus numbers, each of the resulting test scores was converted to a plus score by making a raw score of 0 equal to 20. A minus 5 then became 15, a plus 5 became 25, and so forth.

The test scores resulting from the combined procedure produced the parameters in table 6.

The biserial correlation yielded by these parameters is 0.53 ($\pm .06$). Biserial correlations are not adaptable to prediction formulas and do not yield an error of estimate. However, it is possible to establish a cutoff score that will produce a maximum level of prediction for the scale. In this case a score of 21 or

lower was used for predicting inclusion in the nonaccident group. By using percent of total area under the normal curve between the mean ordinate and an ordinate at a given sigma distance, a success of prediction results, as seen in table 7.

TABLE 6. *Test scores after weighting as described in text*

	Nonaccident group	Accident group	Combined group
Mean	17.99	23.78	20.89
S. D.	6.19	6.33	6.88

TABLE 7. *Success of prediction using method described in text*

Cutoff score	Nonaccident group		Accident group		Percent total correct
	Percent correctly chosen	Percent incorrectly chosen	Percent correctly chosen	Percent incorrectly chosen	
21 - 22	68.79	31.21	61.03	38.97	64.91

These figures are not particularly impressive if one desires to use this scale as a sole means of selecting safe automobile drivers, but it might be of value as part of a test battery after being subjected to sufficient cross-validation. However, it is important to know that a test such as this can produce a correlation that is statistically significant and considerably higher than many that have been reported in the literature. It speaks well for the future development of techniques like the Picture Frustration Study.

On the basis of these figures I have put together a collection of cartoons that deal entirely with highway situations. To date they have been used only clinically, with no attempt at systematic analysis.

SUMMARY AND CONCLUSIONS

Two groups of automobile drivers were given the Rosenzweig Picture Frustration Study in addition to other tests. These groups numbered 67 men each, and were equated according to age, marital status, parenthood, education, intelligence test score, years of driving experience, estimated mileage driven for the last 2 years, and time spent in service. Those in the first group were completely accident and violation free for their entire driving history, while those in the second were involved in at least one recent traffic accident in which they were charged with a moving violation.

The Rosenzweig Picture Frustration Study produced significant differences between the groups only on the basis of the Ego-Defensive and Need-Persistence percentages. In addition, item analysis of the test allowed 10 item scores to be used in differentiating between the groups. By weighting and combining the percentages and item scores it became possible to differentiate between the two groups. The biserial correlation obtained was 0.53 and the efficiency of prediction was 64.91 percent.

While this correlation does not allow the P-F Study to be used as a sole prediction instrument, it does indicate that test items such as those contained in this test have promise for future application to the problem of differentiating between the safe and unsafe automobile driver.

THE ART OF SELF-EXPRESSION

The lack of competence of most physicians as speakers is not surprising. After all, they spend their time doctoring and not orating. Medical teachers need not be orators but they can avail themselves of some of the modern visual aids in teaching and learn some of the rudiments of clear presentation. Too often slides used are so complicated that they merely confuse. Medical movies, colored slides and so forth have great value as adjuncts in teaching. Much assistance in the planning and execution of teaching exercises can be given by a professional organization.

ENURESIS: CLINICAL, LABORATORY, AND ELECTROENCEPHALOGRAPHIC STUDIES

CHESTER M. PIERCE, *Lieutenant (MC) USN*

HARRY H. LIPCON, *Captain (MC) USN*

JOSEPH H. McLARY, *Ph. B.*

HOWARD F. NOBLE, *Lieutenant (MSC) USN*

FROM the most remote times of antiquity, in such diverse civilizations as the Mesopotamian, Hindu, and Greek, physicians have treated disorders of the genitourinary tract.¹⁻³ However, enuresis is one disorder which has baffled medical science for centuries. In his *Natural History*, the Roman Pliny prescribes a course of therapy to eradicate enuresis that includes such measures as the consumption of wood lice and spayed swine's urine.⁴ This is similar to some more present-day treatments in which the unfortunate suffering from enuresis is served fried rats or mouse pie in an effort to effect a cure.^{1,5} Goldman,⁶ in a review of the medical history of enuresis, lists an astonishing number of desperate and drastic treatments extant in the 18th, 19th, and 20th centuries that frequently are without any apparent rationale.

To the United States Navy, the effects of enuresis are tremendous in scope since they include inestimable economic and morale problems. The enuretic is deemed unsatisfactory for sea duty because the confined quarters and lack of ventilation compounds the unsavory ammoniacal odor. The enuretic seaman is subjected to teasing, derision, jibes, and taunts. He may make a valiant effort to break his habit by reducing his water intake and making frequent visits during the night to the "head." As the difficulty persists, however, the man becomes subjected to more intense tirades and even minor aggressions by his shipmates. Furthermore, the sleeping accommodations on board many ships are such that the enuretic's habit would be tangibly objectionable to any man who might happen to occupy a bunk beneath him. The enuretic may become the indirect cause for an impairment in the efficiency of the crew.

These inconveniences to the individual and the group are even more striking when viewed during the process of "boot training." For all men this is, at best, a period of turmoil, but for the enuretic it is a period that presents near-insurmountable adjustment

problems. The competitive, masculine standards of military life will not allow such a blatantly overt manifestation of what is generally considered to be "immaturity." As the enuretic is often responsible for the accumulation of demerits for the entire company, he is liable to become the target for all manner of group dissatisfactions, which are many during the rigorous process of attempting to convert a civilian boy into a military man in a relatively short period. Also, the harassed company commander finds the habit of enuresis particularly offensive, since it reflects on the ideals which he is trying to inculcate in his group. The warrior, stereotypically, is not a bed wetter. Therefore, despite whatever progress in training a man might make, if he is enuretic he has to contend with negative feelings from many sources. Not infrequently, this cumulative stress so taxes his capacity to adjust that all areas of his naval life are adversely affected and he has more difficulty with enuresis. This vicious cycle is so extreme that even a man with many successful ego strengths would be pressed to remain emotionally stable. It must be fully appreciated that the deleterious influence of this vicious cycle on one man so affects his interpersonal relationships that serious disruption of the group results, and consequently its over-all training suffers. For these reasons the enuretic recruit is discharged from the Navy.

Although it is realized that to go home after being in the Navy for only a few weeks may cause serious emotional traumata, such as feelings of self-devaluation and inadequacy, to the youth as he re-integrates into his home community, these matters are beyond the control of the Navy. The youth must handle for himself his own attitudes as well as those arising from injured family pride or from a condescending, patronizing, or hostile community.

PURPOSE

Between 25 February 1954 and 25 February 1955, nearly one out of every 100 men entering naval service at this naval training center was discharged prior to completion of boot camp because of enuresis.⁷ This represents a drain on available manpower, a considerable economic expenditure in transporting and training men who will never contribute to the Navy, and a variety of morale problems. Accordingly, it was considered that the study of enuresis was necessary from a practical viewpoint. Since there is a super-abundance of clinical case material in the military which would not be available to civilian investigators, it was believed also that perhaps some contribution to the further understanding of enuresis might result. Therefore these studies* were made: (1) to determine which, if any, enuretic recruits might be

*The authors wish to express their gratitude to Capt. H. J. Bowen, (MC) USN, and Comdr. A. J. Zuska (MC) USN for their assistance in performing this study.

rehabilitated for service in the Navy, and (2) to discover any objective methods which would aid in the quicker detection of those incapable of being rehabilitated.

In regard to rehabilitation, it is hypothesized that some enuretics might possess enough assets to warrant their retention, even if only in some limited capacity such as permanent shore duty, where they could make definite contributions to the service. In times of complete mobilization, the loss of all enuretics could represent a needless diminution of naval strength. On the other hand, it is important to detect as soon as possible, whether in war or peacetime, those enuretics who are unable to make positive contributions and who are carried along until separated as economic and psychiatric liabilities.

In the first investigation biologic, social, and psychologic factors were surveyed in a comprehensive manner in the hope that further paths of fruitful study would be indicated. Ultimately, we hope to establish a treatment colony that will test the efficacy of various modes of therapy aimed at facilitating the rehabilitation of enuretics. This report is concerned with the findings of clinical, laboratory, and electroencephalographic examination. Future reports of the primary research project will deal separately with psycho-social factors and other research approaches.

DEFINITION

For the purposes of our investigation we shall use Wilson's¹ definition of enuresis: "Enuresis, then, can be defined as bed- or clothes-wetting (in those) above the age of 3, who fail to inhibit the reflex when the impulse is felt during waking hours, or do not rouse from sleep of their own accord when the process is imminent."

MATERIAL

In this primary study we contrasted 60 enuretic recruits with 60 men in Electronics School. Considerable effort was made to be certain that all enuretics actually suffered persistently from this difficulty. Not only did we have observations by company commanders and trained hospital corpsmen, but in each instance, upon the man's admission to the neuropsychiatric unit, a telegram was sent to a social service agency in his home area requesting them to procure information from his family in regard to enuresis. This use of telegraphic confirmation of enuresis was not known generally, so it is unlikely that recruits had any chance to solicit the aid of their loved ones in perpetrating fraud. In addition, there was other evidence besides the admitted history of enuresis, observations by competent persons, and telegraphic confirmation. This evidence included documents filled out by the recruit when he entered the Navy in regard to his past history

of enuresis. At this time, most youths are too motivated for service and too unsophisticated in military ways to plan for an early discharge by falsifying this record. Several recruits were sent for medical evaluation upon discovery of tell-tale mattress rings during inspection by the company commander. We believe that these measures were successful in deleting from the study those youths who purposely wet the bed in an effort to escape from service. The fact that many resort to purposeful bedwetting is a well-known fact to all military and medical officers and has been commented upon frequently in the medical literature. Parenthetically, it might be added that approximately 40 per cent of the telegrams sent out failed to confirm the alleged history of enuresis.

It is regrettable that military circumstances precluded the procurement of a random recruit control group more closely matched to the experimental group. The control group was made up of men who had finished an initial course in mathematics and were ready to enter basic electronics. As will be seen, this control group represented slightly different ranges in age and length of service. A more radical difference can be observed when the geographic and racial distributions of the groups are contrasted. Also, the I Q's of the control group used differed more markedly from those of the experimental than would those of a random group. However deplorable this situation might be from a scientific viewpoint, the groups used do consist of individuals regarded as unsuitable for service and those regarded as highly suitable. The Electronic School represents one of the most coveted service school assignments, and the caliber of its candidates is the highest, generally, that can be found among enlisted men.

METHOD

A three-part procedure was used in this investigation. On both experimental and control groups the following studies were carried out: (1) electroencephalographic examination, (2) administration of a battery of psychologic tests, and (3) psychiatric interviewing. This article will discuss only the electroencephalograms and the clinical and laboratory findings.

The electroencephalographic tracings were all made on an Offner type ink-writing oscillograph with the technic of 12 lead monopolar and bipolar recordings, bilaterally, from the frontal, parietal, and occipital areas. All the recordings were made within a period of three hours after eating.

It may be assumed fairly that all men in the study were in "normal health," since they had all undergone recent, thorough physical examinations. The population we were dealing with and the fact that its members were able to participate actively in

military service is functional evidence of good health. To control the study, however, diligent inquiry into the past history of sickness, injury, and circumstances of birth of all the men was made. Particular emphasis was placed on any periods of unconsciousness and on positive findings in the review of the genitourinary system. Any family history of enuresis or of convulsive disorders was also carefully sought. The findings elicited from this inquiry are summarized in table 1. Neurologic examination was performed on each man. On approximately one third of the men from each group, voided specimens of urine were obtained at random and studied.

RESULTS

No significant abnormalities were found by physical or neurologic examination in any person included in this report. Three enuretics and one of the controls showed absence of a cremasteric reflex; these men had been subjected to herniorrhaphy. One enuretic and one control claimed to have anosmia and were discovered by routine tests (tobacco, cinnamon, nail polish) to have some gross impairment in olfactory sensation. The enuretic was suspected of malingering, and the control dates his anosmia from a rhinoplasty. One enuretic and one control were judged to have nystagmoid motion on lateral gaze, and in each case it was presumed to be congenital. One control showed some sequelae from a severed left ulnar nerve. Another control persistently demonstrated marked increased muscle strength throughout the right side of his body. All these men had negative electroencephalograms and negative urinary findings by history and by urinalysis, if performed.

Two enuretics, however, were noted to have divergent strabismus. One had an abnormal brain wave and complaints of frequency and urgency; the other had a negative brain wave and negative urinary findings.

Only 1 (1.7 per cent) of the controls showed a borderline electroencephalogram; 59 readings were interpreted as normal. Fifteen (25 per cent) of the enuretics, however, had other than normal electroencephalograms. Of these, two were read as borderline, while 13 were abnormal; all were characterized generally by a poorly regulated and poorly developed alpha rhythm of about 8 to 10 per second. The location of the abnormality was always in the anterior and posterior portions of the head, and the speed, typically, had slow activity of about 5 per second. Upon hyperventilation, there was consistent building up of the amplitude and a slowing of waves to about 4 per second. The single borderline control record demonstrated 10 per second alpha rhythm in the anterior and posterior portions of the head, with slow activity (5 to 6 per second) of mildly increased amplitude. It was of interest that the control showing a borderline electroencephalogram had been enuretic until the age of 15 and had immediate family members who wet their beds.

A review of the genitourinary system of 60 controls revealed four isolated complaints. None of these complaints were of present interest to the subject. The enuretics, however, registered 76 complaints, nearly all of which were of current and life-long concern to the subjects. The control subject with the borderline electroencephalogram had no complaints. The type and frequency of these complaints in both groups are outlined in table 2.

Urinalyses were done on 26 men in the experimental group and on 20 men in the control group. The research design calls for more careful attention to qualitative and quantitative urine observations in the future; these specimens were done merely to see if any detectable trends were apparent. In addition to the findings in table 3, the enuretics' urine showed three times as many cellular casts (27:8).

Table 4 summarizes the statistical treatment of the electroencephalographic relationships.

Each of three enuretics was a member of a set of twins. None of the controls had co-twins. Two enuretics were fraternal twins. Both of these men had negative brain waves, but one had an enuretic co-twin. The third enuretic, who had an identical twin (who was not enuretic), had an abnormal brain wave.

Two enuretics had been delivered at birth by cesarean section. Like the one control who had been delivered in this manner, they had normal brain waves. One enuretic had been delivered by

breech and he, too, had a normal brain wave. One enuretic stated that both he and his mother were uremic at the time of his birth. He had an abnormal brain wave and was ostensibly "organic" on direct examination of the mental status. A random blood urea nitrogen determination on this man was 20 mg per 100 ml, and he complained of urgency and difficulty in initiating micturition.

Most of the controls having a history of unconsciousness from causes other than fainting had been knocked out while engaged in sports. None of them seemed to have suffered epileptic seizures. Five of the enuretics who had lost consciousness from causes other than fainting seemed to have had seizures of some sort.

DISCUSSION

An integrated commentary at this juncture in our studies is not possible. Also, many of the most enlightening observations made during this experiment are based on the psychologic and psychiatric data. Much of what has been indicated by this particular phase of the study will be thoroughly discussed in our report concerning research suggestions.

Readers outside the field of neuropsychiatry may not be fully aware of the implications of anosmia. Anosmia often is the only symptom of olfactory meningioma. This tumor has been called the most important in psychiatry since its mental manifestations are protean and it is frequently remediable by operation.^{9,10} In a study of electroencephalograms, accordingly, one must be alert to this diagnosis in the evaluation of data. By means of thorough roentgenographic and clinical examinations we believe we excluded the possibility of this tumor in this series of cases.

Another point to consider is the medical histories of subjects undergoing electroencephalographic examination. Of the 10 enuret-

ics suspected of or treated for epilepsy (table 1), five had family members definitely diagnosed as epileptic. Seven of the 10 had abnormal brain waves. In the controls there were no personal histories suggestive of epilepsy and only one situation of a family member being treated for epilepsy. The contrast in these groups forces one to recall the oft-quoted dictum of Freud that nocturnal enuresis, unless epileptic, must be considered a "pollution."¹¹

Eminent medical scholars have wondered if the electroencephalographic pattern could be an hereditary trait and an indirect index of cortical metabolism,^{12,13} while other investigators have satisfied themselves as to the existence of central nervous system pathways and nuclei which regulate micturition.¹⁴⁻¹⁶ The integrity of these multiple centers is regarded as essential for normal micturition. Regulatory controls for the voluntary detrusor vesicae and external and internal sphincters, as well as for subcortical centers, sensory centers, and nuclei for correlation, have been described. These centers are variously located in the precentral gyrus (detrusor vesicae and external sphincter), paracentral lobule and outer sigmoid gyrus (internal sphincter), cerebral peduncle, thalamus, and corpus striatum (subcortical centers), frontal lobe, cerebellum, and corpus striatum (nuclei for correlation), and midbrain and gyrus fornicatus (sensory centers).

The significant preponderance of abnormal brain waves in the chronic adolescent male enuretics whom we have studied strongly suggests that an organic factor must be considered in determining the causes of enuresis. Further evidence of this factor is adduced from the fact that 75 per cent of enuretics had a family history of enuresis.

Confirmation of findings by other workers in regard to the presence of abnormal brain waves in enuretics is made by our investigation. Turton and Spear¹⁷ reviewed the literature on this subject and presented their findings of 51 abnormal electroencephalograms from a study of 100 severely enuretic children. They, too, concluded that in many cases of enuresis there must be a physical basis for the symptom. There are other organic factors assumed to be causes of enuresis, such as urethral strictures and congenital defects, that are beyond the scope of this article because they do not specifically involve electroencephalograms.

After studying the pedigrees of 59 clans, Frary¹⁸ in a classic work hypothesized that enuresis is determined by a single recessive gene substitute. Most workers in the field have decided that there apparently is a familial aspect to enuresis, although many attribute this to sociocultural influences, while many others merely note the relationship. We found exactly the same percentage of positive family histories that Levine⁹ noted in his study of 150 enuretic sailors during World War II.

The abnormal electroencephalogram and a family history of enuresis indicate a factor of organicity, although the causes of enuresis seem to be numerous. We would like to suggest a third possibility which should be further developed. Recently, a resourceful investigation has shown, by means of electroencephalograms and electromyograms, that the enuretic is physiologically awake at the time of wetting.¹⁹ We shall not enter at this time into the controversy as to whether or not the enuretic is a "heavy sleeper." However, sleep disturbances may be characteristic of the enuretic and may be a direct and measurable result of an inherited gene pattern. The distorted gene pattern might cause abnormal brain waves, as well as sleep disturbances such as night terrors and somnolence, which have been known for many years to occur in enuretics.²⁰

There has been little commentary in the literature concerning the occurrence of sleepwalking in enuretics. Berdie and Wallen²¹ found that their enuretic marines were more likely to sleepwalk than a matched control group, but they did not give numerical information. Unpublished data that we are now collecting would indicate that adolescent male sleepwalkers commonly have a problem of enuresis. In our study it was found that a significantly large number of enuretics were sleepwalkers.

Perhaps a neurophysiologic explanation for some cases of enuresis will result from increasing knowledge of those factors in the reticular brain stem formation which manage the state of wakefulness.^{22, 23} Theoretically, genetically determined, anatomic impairment might explain in some cases the occurrence of enuresis and the clinical observations of abnormal brain waves, the high correlation of positive family histories of enuresis, and the proclivity to sleep disturbances.

Evaluation of the urinary findings is difficult. Creevy¹⁵ discusses the effect on micturition of lesions in the nervous system. He quotes also from the literature concerning the effects of brain lesions on bladder disturbance. The methodologic troubles secondary to producing specific lesions in mixed motor-sensory nerves makes judgment of experimental results difficult. Nevertheless, one is reminded of the enuretic's complaints of frequency, dysuria, and urgency when he considers that these complaints are sequelae to sensory or motor irritation in the nervous system. Of course, it is very likely that the enuretic dwells more consciously on the malfunctioning of his renal system, for an organic lesion would provide a socially acceptable explanation for his "weak kidneys." In talking to hundreds of enuretics, however, we have gained the opinion that in many cases much of the preoccupation with genitourinary problems has an authentic organic basis. We must defer at this time a consideration of how this may relate to brain waves or to urinalysis findings.

SUMMARY

The importance of enuresis as a military problem is discussed. A survey of possible organic, psychic, and social factors in etiology was undertaken in an effort to determine which enuretics could be salvaged for the Navy and what treatment methods might be used for this purpose.

Study of 60 enuretic recruits and 60 nonenuretic Electronic School students reveals that more enuretics have abnormal brain waves (25 per cent to 1.7 per cent), more enuretics have relatives who are enuretic (75 per cent to 16.7 per cent), enuretics have more problems with sleepwalking (26.6 per cent to 3.3 per cent), more genitourinary complaints (76:4), and there is evidence suggesting that enuretics' urine is qualitatively different.

It is postulated that in the chronic adolescent male enuretic, a factor of organicity must be reckoned with in the consideration of causes, although there must also be multiple factors of a "functional" nature.

WHAT CHILDREN INHERIT

Children acquire the quality of dominance or submission characteristic of the parent of the same sex and the quality of hypoordinacy or hyperordinacy characteristic of the parent of the opposite sex, if they have no older siblings of their own sex. Succeeding children are usually opposite in temperament from the preceding sibling of the same sex if this preceding sibling is not more than a few years older.

p. 501, Dec. 1954

BEHAVIOR

"Biology supplies an arm and fingers, a skeleton and muscles, and a reflex and 'voluntary' control of movement; but it cannot yet account for the individual characteristics of each person's handwriting. Biology can pretty well characterize the violin but is only on the edge of understanding why one plays sweetly, another not. The biologist is happy to recognize that two men or two violins are more like each other than like anything else in the world; psychiatric practice takes the violin for granted and is concerned with the sour notes that come from certain ones. Biological science seems to deal with the Cheshire cat; mental science, with its smile."

THE NEW RAPID TEST FOR BILIRUBINURIA

Its Usefulness In Hepatitis

WILLIAM S. HAUBRICH, *Captain, MC, USAR*

With the Technical Assistance of
A. E. Lister, *Sergeant, first class, Medical Service, USA*

OBJECTIVELY, acute hepatitis is characterized, in successive phases, by bilirubinuria, increased urinary urobilinogen, elevated concentration of serum bilirubin, aberrations in the several flocculation tests, and abnormal retention of injected sulfobromophthalein. In the absence of a specific test for viral hepatitis, these determinations are of value not only in the diagnosis of the disease but also in following its course. Of the parameters listed, bilirubinuria usually is the first which may be detected and one of the most consistent through the course of acute hepatitis.

Recently, there has been made available a simple, rapid test for the detection of bilirubinuria, based upon the property of bilirubin to couple with diazo compounds to produce a characteristic color reaction.^{1,2} The active reagent (*p*-nitrobenzene diazonium *p*-toluene sulfonate) is incorporated in a stable tablet* which is used in a manner similar to the well-known tablet tests for sugar, acetone, and blood. The test requires only the tablet, a suitable mat (supplied with the commercial package containing the tablets), and water; the result is available in 30 seconds.

The purpose of this study was to correlate the presence of bilirubinuria with the concentration of serum bilirubin and the clinical course of hepatitis as observed in hospitalized patients.

MATERIAL AND METHODS

Clinical and laboratory observations were made on 50 unselected patients of the gastroenterology service in this hospital

From Madigan Army Hospital, Tacoma, Wash. Dr. Haubrich is now at The Henry Ford Hospital, Detroit 2, Mich.

*Manufactured under the proprietary name "Ictotest" by the Ames Company, Inc., Elkhart, Ind. The item is available from the Armed Services Medical Stock List (Stock No. 6505-290-6031, Bilirubin Test Kit, 90 diazonium tablets and 90 absorption mats).

because of liver disease during the year prior to 1 May 1955. The series included 40 patients with acute viral hepatitis, presumably of the IH type; the remainder had protracted hepatocellular disease, *e. g.*, Laennec's cirrhosis, fatty metamorphosis of the liver, and chronic hepatitis. Serial determinations of serum bilirubin, thymol turbidity, cephalin-cholesterol flocculation, sulfobromophthalein retention (in the absence of jaundice), and the urinary concentrations of bilirubin and urobilinogen were recorded at intervals of one week or less. The tablet test for bilirubinuria was performed according to the method described in detail by Giordano and Winstead.² Almost 1,000 tests for bile in the urine were performed by this method in the course of this study.

RESULTS

Bilirubinuria was detected in all cases of acute hepatitis during the icteric phase of the disease. Of 169 simultaneous determinations of bilirubin in both the serum and urine, 8.3 per cent of the reactions were recorded as negative for bilirubinuria in the presence of elevated serum bilirubin concentrations. In 14.2 per cent of the determinations, a positive reaction for bile in the urine was obtained when the serum bilirubin concentration totaled less than 1.2 mg per 100 ml; however, in only two of these patients was the "direct-reacting" fraction less than 0.2 mg per 100 ml. A general, although inconsistent, correlation was observed between the concentrations of serum bilirubin and the quantitative estimation of bile in the urine (fig. 1).

Without exception, the tablet test for bilirubinuria was positive in patients with acute hepatitis at the time of the patient's admission to the hospital. In almost all patients bilirubinuria was consistently present through the overtly icteric phase of the disease even though the patient's urine had resumed a normal color to casual inspection. In the group of patients with acute hepatitis admitted directly from the unit dispensaries, an elevated serum bilirubin persisted for an average of 27.2 days. In about two thirds of the patients, bilirubinuria disappeared shortly prior to the return of serum bilirubin to normal. The course of the disease, as observed in this group, was comparable with that succinctly depicted in the official monograph dealing with infectious hepatitis.³

Comment. The rapid tablet test has been established as a sensitive and reasonably reliable detector of bilirubin in the urine, and it has been demonstrated to compare favorably with the more cumbersome, orthodox Watson-Hawkinson and Harrison tests.^{1,2} In our experience, we have found the test easy to set up and to read, and remarkably adaptable to the patient's bedside, the physician's office, the dispensary, and the field. The

sensitivity of the reagent is attested by the observation that a positive color reaction is obtained within 30 seconds on the addition of urine containing as little as 0.05 mg of bilirubin.² At the same time, caution must be exercised to avoid misreading as "positive" a faint pink blush which may appear at the base of the tablet with addition of water or a color reaction which appears after 30 seconds.

Figure 1. Scattergram depicting the correlation in 169 simultaneous determinations of bilirubin in serum and urine taken from patients with active hepatocellular disease. At the ordinate, P denotes positive and N denotes negative; to the left and below the broken lines lie normal values.

DISCUSSION

Usefulness of the Test in Diagnosis. By analysis of our cases of acute viral hepatitis observed within the past year, we have found the first symptoms of the disease develop on an average of 7.5 days prior to the patient's admission to the hospital. Invariably these symptoms were protean with rarely a suggestion that frank hepatitis was to ensue within little more than a week. It was during this prodrome that the soldier usually presented himself for the first time to the unit dispensary. It is little wonder that in almost every case, in the absence of more definitive signs, he was returned to duty and received only symptomatic treatment.

It is noteworthy that we found "dark urine" to have been observed by the patient on an average of 5.5 days prior to admission. In almost all cases this was the first definitive sign of liver disease. Curiously, the patient seldom related this observation voluntarily, and only by direct questioning could this sign be elicited. In only two patients was the appearance of "dark urine" delayed until the onset of overt jaundice; in the remainder, "dark urine" preceded awareness of jaundice by an average of 3.9 days. Jaundice was detected, either by the patient, his buddies, or the physician, only 1.7 days, on the average, prior to hospitalization.

From the analysis (fig. 2) it is obvious that the best opportunity by which to establish a presumptive diagnosis of hepatitis

Figure 2. Diagram illustrating the course of acute viral hepatitis as observed in the group of patients described in this study. Particular reference is made to the sequence of bilirubinuria and hyperbilirubinemia. The asterisk denotes the important interval during which bilirubinuria may be the sole definitive sign of the disease in the preicteric phase.

in the preicteric phase lies in the four days during which bilirubinuria is the sole and only easily detected, definitive sign of the disease. How often is the medical officer in a quandary regarding the possible existence of acute hepatitis in the soldier complaining of nondescript malaise, anorexia, nausea, and vomiting? Given this meager information alone it is exceedingly difficult to assign an accurate diagnosis. In such a case, however, when one can determine objectively the presence of bile in the urine, the diagnostic problem may be resolved. The prompt

detection of hepatitis will result in earlier hospitalization and the institution of appropriate supportive treatment, which can favorably affect the subsequent course of the disease. Further, such early detection more quickly withdraws the soldier who harbors the virus from his unit organization and could be expected to diminish the likelihood of contagion.

Usefulness of the Test in Following the Disease. In observing the course of acute viral hepatitis, a series of sequential "milestones" is customarily noted. With the advent of frank jaundice usually the subjective discomfort of the patient remarkably subsides. Nausea is abated, appetite returns, the notorious distaste for tobacco disappears, and the distress in the right upper abdominal quadrant, if present, diminishes. In our group of patients, with only two exceptions, the peak concentration of serum bilirubin was recorded at admission, and almost invariably the jaundice gradually diminished following institution of the "liver rest and support regimen." In sequence, the next observation is usually an apparent return to normal in the color of the urine. However, in our series, "occult bile" by chemical test remained even though the urine appeared to be of normal color. Grossly apparent jaundice then disappeared although the serum bilirubin concentrations slightly exceeded normal values. Bilirubinuria cleared in an average of four days before the serum bilirubin reached normal levels in both the "direct" and "indirect" fractions. For an unexplained reason, in about one third of our patients, bilirubinuria persisted beyond the return of serum bilirubin to normal. Perhaps this reflects an altered renal threshold for bilirubin.³ Finally, the sulfobromophthalein retention test, that we use after overt jaundice has disappeared, remains elevated usually one or two weeks.

Usually when the findings of the serum bilirubin concentration test approach the normal, we permit the patient to begin progressive ambulation. When the sulfobromophthalein test returns to normal, the patient is usually released from the hospital. We find we are neither justified nor required to insist upon normalcy in the flocculation tests before returning the patient to duty. Often there is an inordinately protracted period during which these tests may remain "positive" and yet during which there is no other sign of activity of the disease.

With this sequence of events, we have found the rapid test for bilirubinuria to furnish us with a signal, in the absence of overt jaundice, that the serum bilirubin may be expected to reach a normal concentration within a short interval. This may permit slightly earlier ambulation and subsequent rehabilitation in a majority of patients.

SUMMARY AND CONCLUSIONS

Experience with a new, rapid test for bilirubinuria (ictotest) is described in a relatively large group of patients with acute viral hepatitis. We have found the test simple, sensitive, and reliable. There is a reasonably good correlation between bilirubinuria as detected by this test and relative concentrations of serum bilirubin.

The test should be of primary value in the early detection of acute viral hepatitis prior to the frankly icteric phase, thus facilitating earlier hospitalization and treatment. It is helpful in following the course of the disease and often heralds the return of normal serum bilirubin concentration. This may serve as a criterion for beginning progressive rehabilitation of the patient.

A PHYSICIAN'S TRUE WORTH

The great strides in medical knowledge have come through the voluntary efforts of the individual. Once an idea has been shown to have merit, its sponsor has generally won the material support necessary to develop the idea. Remember, pain is not deterred by race, creed, wealth, or poverty. Medicine and surgery know and are restrained by no boundaries. A physician's true worth lies in his knowledge and understanding of things of the past and those of today, combined with his ability to anticipate tomorrow's need and apply the sum total in the care of and for the welfare of the patient at hand.

ARTHRO-ONYCHODYSPLASIA

A Hereditary Syndrome

HAROLD BRODER, *Captain, USAF (MC)*

A HEREDITARY syndrome consisting of an unusual combination of skeletal disorders forms the basis for this report. Bilateral posterior dislocation of the radial head, hypoplasia and lateral dislocation of the patellas, dystrophy of the nails, and a horizontal sacrum were discovered during the examination of a young airman. Similar abnormalities existed in an older brother and had been present for three known generations of the same family.

CASE REPORTS

Case 1. A 17-year-old man sought advice at this hospital because of pain and swelling in the knees after marching and prolonged standing. These symptoms had been noted following excessive activity for many years. Physical and roentgenographic examination revealed the following: (a) *Knees*—knobby in appearance (fig. 1); very small patellas articulating with lateral aspect of lateral femoral condyle; shallow articular groove on lateral femoral condyle for patella (fig. 2); downward and oblique lateral pull of quadriceps tendon; shallow, empty, palpable intercondylar notch of the femur; prominent medial femoral condyle; prominent tibial tubercle with lateral displacement; active motion, 160° to 45°; passive motion, 185° to 45°; no ligamentous instability. (b) *Elbows*—radial head prominent posteriorly at level of upper end of olecranon; atrophy of capitellum (fig. 3); limitation of terminal 15° of extension, pronation, and supination. (c) *Nails*—absence of both thumb nails; grayish discoloration and longitudinal ridging of other nails of hands and feet. (d) *Back*—severe lumbar lordosis; horizontal sacrum (fig. 4). (e) *Legs and feet*—external rotation deformity of leg, 45°; secondary varus of feet (in order to point the feet forward in walking).

Case 2. The patient's 21-year-old brother had similar defects of the right elbow, knees, nails, and spine. The complaints again were limited to the knees (fig. 5).

The maternal grandfather and mother were both affected as were our patients. They were dead, however, and their histories could not be confirmed by examination. No information was available concerning the grandfather's forebears. An older brother and

From U. S. Air Force Hospital, Parks Air Force Base, Calif.

a younger sister of the mother were unaffected. An older sister and younger brother of the third generation were entirely normal.

Figure 1 (case 1). Patient with arthro-onychodysplasia. Note knobby appearance of knees, external rotation of legs, posterior prominence of radial heads.

DISCUSSION

While isolated hereditary posterior displacement of the radial head, patellar dysplasia with or without dislocation,¹⁻³ dystrophy of the nails⁴⁻⁶ and horizontal sacrum are not uncommon, their combined appearance as a familial disorder is exceedingly rare. A hereditary triad characterized by posterior dislocation of the radial head, hypoplasia with lateral dislocation or absence of the patella, and dystrophy of the nails has been described by Aschner,⁷ Bates,⁸ Lester,⁹ Montant and Eggerman,¹⁰ Senturia and Senturia,¹¹ Sever,¹² Turner,¹³ and Wildervanck.¹⁴ The triad is generally present in its entirety or in part in some members of successive generations. Turner described one family in which

Figure 2 (case 1). Anteroposterior view of knees. Note hypoplasia and lateral position of patella, external rotation of tibia and fibula.

Figure 3 (case 1). Lateral view of elbows, showing position of radial head.

the arthrodysplasia and nail dystrophy were found in 26 of 39 members, and a second family in which 27 of 41 suffered nail dystrophy but only nine of these had the arthrodysplasia. Aschner, Senturia and Senturia, and Turner believe that the genealogy in this syndrome is of the non-sex-linked, dominant variety. Aschner has postulated that, "With such rare deformities it cannot be merely by chance that these defects are inherited together." She has explained the clinical data known about the syndrome by the phenomenon of linkage, with close neighborhood of linked characters.

Figure 4 (case 1). Lateral view of lumbosacral spine, showing horizontal position of sacrum.

The defects are carried simultaneously by the mesoderm and ectoderm in three closely linked pathological factors. Since the triad does not appear as frequently as the combination of nail and patellar dystrophy, there must be a more intimate linkage between the genes for the patella and the nails than for the radial head. Other less plausible theories have attributed the anomalies to a single gene, or to a third inhibiting factor which is responsible for the arthrodysplasia when absent. Various supplementary anomalies have been described with the basic triad. Turner reported a dark, clover-shaped central ring in the iris about the pupil, an increase in the normal concavity of the external surface

of the ilium, and various minor bony aberrations about the shoulder girdle in some cases. In a patient described by Bates, "iliac horns" accompanied the syndrome. No previous record of a horizontal sacrum accompanying the triad could be found.

Figure 5 (case 2). Anteroposterior view of knees, showing particularly the shallow articular groove present on lateral aspect of lateral femoral condyle for articulation with the patella.

SUMMARY

An unusual hereditary syndrome, characterized by various combinations of dysplasia of the elbows and knees and dystrophy of the nails, is discussed. Four members of a family in which the triad has been transmitted through three known generations are reported. The sole disabling feature in the two living members was directly caused by the knee anomaly. Both the knee and the elbow abnormalities would be amenable to improvement by surgical correction at an early age.

MEDICINE IN THE NEWS

We recognize that the public is interested in all things medical, particularly new and promising procedures. They are intrigued by articles on medical subjects that become available to them. No one should object to the dissemination of newsworthy information but it should be mature and reliable. Spectacular journalism should be discouraged. The physicians themselves are the most reliable sources of trustworthy information. We should furnish material on new or interesting medical subjects because it will tend to discourage some of the zealous lay writers and it will maintain the confidence and friendship of the people as patients.

GASTRO-INTESTINAL PROBLEMS IN CHRONIC PULMONARY DISEASE

JAMES C. SYNER, *Captain, MC, USA*

IN treating patients with chronic pulmonary disease, problems involving the gastro-intestinal system arise which significantly affect the management of the total patient. Frequently the patient's primary concern is with his gastro-intestinal difficulties, while the physician concentrates on the pulmonary abnormalities. This is because the physician tends to focus on "findings" whereas the patient will focus on "symptoms." This is strikingly illustrated by the patient with bronchiectasis who is concerned with loss of appetite, "no taste" for his favorite foods, and weight loss, while the physician evaluates bacterial flora, character and amount of sputum production, and abnormal pulmonary physiology. Awareness of the patient's concern, apprehension, and anxiety over such difficulties is fundamental to optimum management of the total patient.

SCOPE OF THE PROBLEM

This presentation will be limited to gastro-intestinal problems secondary to a primary pulmonary disease, thereby excluding the following:

1. Gastro-intestinal problems arising either as a direct result of generalized systemic toxicity and spread of the primary process or from treatment complications in acute pulmonary diseases. This is illustrated by a staphylococcal pseudomucinous enterocolitis reported as a complication of antibiotic therapy employed to treat an acute, toxic lobar pneumonia in a patient without an underlying chronic pulmonary disease. Complications of this nature following the use of antibiotics have been reported previously.¹⁻³

2. Chronic pulmonary disease resulting from a primary gastro-intestinal problem. This is illustrated by a bronchiectasis resulting from diseases of the esophagus, such as cardiospasm, peptic esophagitis with obstruction, and diverticulum producing recurring contamination of the pulmonary tree by secretions and food particles infected by mouth bacteria.⁴

3. A major form of anatomic disease demonstrated in the gastro-intestinal tract in a patient with a chronic pulmonary disease,

From Walter Reed Army Hospital, Washington, D. C. Capt. Syner is now assigned to Fitzsimons Army Hospital, Denver, Colo.

February 1956)

where no causal relationship between the two could be found. This is illustrated by a gastric cancer, peptic ulcer, cholelithiasis, et cetera, in a patient with a chronic pulmonary disease.

METHODS AND MATERIALS

The data herein presented were obtained from a review of 604 patients managed on either an outpatient or inpatient basis in the medical chest section of this hospital. The presentation will be made in reference to two basic categories:

1. Gastro-intestinal problems arising directly from the disease process, for example, an inguinal hernia resulting from severe, explosive, paroxysmal cough in chronic bronchitis.

2. Gastro-intestinal problems arising as a complication of therapy, for example, nausea attending the use of potassium iodide.

The following criteria are applicable to the patients included in the statistical count:

1. The term "problem" is herein defined to be inclusive of both "signs" and "symptoms."

2. Patients have been followed over the course of several visits and/or hospitalizations in the medical chest section.

3. The pulmonary problems are of long standing, commonly of several years' duration.

DETERMINATION OF THE DIAGNOSIS

The cases presented herein include most of the usually encountered forms of chronic pulmonary disease (table 1). All diagnoses were well documented by careful, prolonged clinical observation and appropriate laboratory data. In almost all cases of bronchiectasis included in the article, a positive bronchogram demonstrating the characteristic anatomic changes supported the clinical diagnosis. In the few patients lacking bronchographic examination, evidence of ectatic degeneration was convincingly indicated by the clinical course, frequency of intercurrent respiratory infections, amount and character of sputum production, lung markings on roentgenograms, and moist, bubbling-type rales on auscultation.

Because of the natural history of the process and the characteristics shared by the three most commonly occurring diseases (table 1), careful consideration was given to the criteria herein accepted for establishing the final diagnosis. This was necessary because of the common occurrence of bronchospasm in bronchitis and emphysema, and the fact that a severe, persisting asthma or bronchitis finally can evolve into a state of progressive emphysematous decompensation. In this phase of the disease process the major problem is the emphysema and is to be so counted for

the record. The criteria and clinical features used in this presentation are discussed in detail elsewhere,⁵ and are in close agreement with those recorded in previous reports.⁶⁻⁷ The fundamental "ground rule" for handling this problem is that "all that wheezes and squeaks is not asthma."

TABLE 1. *Diagnoses in 616 patients with chronic pulmonary disease reviewed for incidence and nature of gastro-intestinal problems*

Diagnosis	Number of cases	Percent of total
Bronchitis	195	31.65
Asthma	87	14.12
Emphysema	60	9.74
Tuberculosis	55	8.92
Bronchiectasis	47	7.63
Coin lesions	36	5.84
Hilar adenopathy	34	5.61
Pulmonary sarcoidosis	30	4.87
Bronchogenic carcinoma	18	2.92
Pulmonary fibrosis	18	2.92
Giant air cysts	12	1.93
Fungus		1.45
Histoplasmosis	4	
Coccidiomycosis	3	
Blastomycosis	2	
Pectus excavatum	8	1.29
Dorsal kyphoscoliosis	4	.64
Primary pulmonary hypertension	2	.32
Pulmonary arteriovenous fistula	1	.16

In our experience, pulmonary fibrosis, to some small degree, is a very common occurrence in patients with chronic pulmonary disease. It was so diagnosed for this study only when it was found to be the major pathologic change. A criterion of major significance in this diagnosis was a reduction of at least 1,000 ml in the total lung volume as determined by pulmonary function studies.

GASTRO-INTESTINAL PROBLEMS AND RELATION TO PULMONARY DISEASE

It is not a difficult matter to relate gastro-intestinal problems to treatment measures for pulmonary diseases. There is almost always a clear-cut relationship between the initiation of treat-

ment, the onset of complications, and the clearing of the difficulties on the withdrawal of therapy. In the absence of this cause-and-effect relationship between treatment and complications, it is very difficult to screen significant symptoms in patients who have chronic disease. The question arises whether it can be determined positively that symptoms arising in other bodily systems are the direct result of a chronic process elsewhere. This consideration entails an evaluation of the role played by functional (psychiatric) disturbances in giving rise to widespread symptoms and somatic reactions outside the system immediately involved. No attempt has been made to sift out functional from organic causes in the problems listed. Each complaint must be evaluated and analyzed in relation to the total problem. I prefer to adopt the point of view that the problems are of mixed origin, being both functional and organic. The implication is that in the absence of the chronic pulmonary disease the gastro-intestinal problems might not have arisen. Anorexia is a classical illustration of this consideration and will be discussed in detail in relation to chronic suppurative disease of the lungs.

Deciding what was to be counted as diarrhea posed certain difficulties. Two or three soft stools per day, even though representing a change from usual bowel habits, was not considered to be diarrhea. The presence of multiple, watery, painfully cramping bowel movements were the features characterizing diarrhea as used for this presentation. This is important in counting complications to broad-spectrum antibiotic therapy, for the presence of two or three soft stools per day, without abdominal cramping, was a rather common finding, whereas the presence of multiple, watery, painfully cramping bowel movements necessitating interruption of therapy was not a frequent complication.

The gastro-intestinal problems encountered and their incidence in the 616 cases are listed in table 2. The three occurring most commonly accounted for 68 per cent of the total complaints. Their distribution as complications of the disease or treatment measures also is given in table 2.

The counts on anorexia, nausea, and vomiting may appear higher than those observed by others. It may be that factors peculiar to mess procedures in the military were involved. However, conducting this review emphasized the importance of specifically interviewing the patient about problems outside the system of chronic involvement. The systemic review must be repeated frequently in following a patient with chronic disease. A great deal can pass unnoticed if one waits for the patient to volunteer information.

ANALYSIS OF GASTRO-INTESTINAL PROBLEMS

Anorexia, nausea, vomiting

In patients with chronic suppurative disease, anorexia is a common complaint. It is usually not a chronic problem, but reappears with enough frequency to concern the patient, provoke weight loss, and necessitate medical help and advice. The patient states the problem as *one of experiencing a sensation of hunger which is lost almost immediately on sight of food or soon after a few mouthfuls have been taken*. It is found more commonly in

TABLE 2. *Type, frequency, and probable cause of gastro-intestinal problems in 616 patients treated for pulmonary disease*

Problem	Number due to treatment	Number due to pulmonary disease	Total
Anorexia	23	95	118
Nausea	41	21	62
Vomiting	25	12	37
Abdominal pain	16	8	24

Total	118	173	291

patients with bronchiectasis than in those with bronchitis, and particularly among those who produce copious amounts of foul, purulent, greenish sputum. Several factors, such as foul mouth taste, psychologic disgust toward raising sputum, and the effect of purulent sputum on gastric mucosa could be considered as causes. The association between gastro-intestinal complaints and the swallowing of purulent sputum has been previously re-

ported.¹⁰ These authors described the results of gastrosopic examination and smears of gastric secretions in 17 patients with chronic pulmonary suppurative disease. Gastrosopic examination was normal in all but two patients, who demonstrated mucosal edema of the gastric antrum with localized atrophic gastritis. The authors did not consider these gastric mucosal abnormalities as being significant, since mucosal edema is a transient phenomenon which does not mean organic disease. These two patients did not have complaints. Six patients who did have gastro-intestinal complaints had normal gastrosopic and gastric-smear findings. Bockus¹¹ has stated that constant swallowing of mucopurulent material may develop chronic gastritis if achlorhydria is present.

A number of patients had linked their anorexia to the absence or diminution of taste. This could well be a complication of the chronic nasal involvement in patients with chronic bronchitis and bronchiectasis. The nasal mucosa appears edematous, inflamed, thickened, granular, covered with tenacious mucoid or purulent sinus drainage, and frequently presents the boggy, bluish discoloration associated with allergic disease. These changes could certainly inhibit the optimum function of the olfactory modality.

Nausea and vomiting have been infrequent findings in bronchitis and bronchiectasis. When they do appear it is usually in this sequence: a paroxysm of severe coughing, retching, and finally the production of vomitus. The patient may describe the experience as the "dry heaves." Some patients will vomit during and following the production of copious, foul, purulent sputum.

In emphysema, especially in advanced cases, anorexia is a frequent problem. Nausea and vomiting are infrequent. Most likely anorexia is the result of an uncomfortable feeling of fullness and distention after a few mouthfuls of food have been taken. The more advanced the degree of emphysematous decompensation, with flattened, fixed diaphragms and labored, fatiguing abdominal breathing, the more marked is the problem.

In the terminal stage of bronchogenic carcinoma, anorexia is almost always present. Nausea and vomiting are not infrequent, but are undoubtedly limited by the patient's restricted oral intake. The size of the pulmonary lesion does not appear to bear a relationship to these particular problems.

When pulmonary sarcoidosis is accompanied by significant parenchymal involvement of the lungs, anorexia can be a very troublesome problem. In particular, anorexia has been more frequent and severe when pulmonary function is significantly diminished. That it might be related to widespread visceral involvement cannot be ruled out. To date, about 75 per cent of our patients who had pulmonary sarcoidosis and who have had a biopsy of a

specimen of the liver had hepatic sarcoid with noncaseating granulomatous tubercles. Palmer¹² has demonstrated this kind of granulomatous lesion in biopsy specimens from the gastric mucosa.

Abdominal pain

This complaint is usually related to treatment measures (table 2). In cases where it was thought to be due to the disease process, severe, explosive cough seemed to be the common denominator. The effect of flattened, fixed diaphragms and labored abdominal breathing in emphysema may be responsible. The areas of pain are usually the costal margin and midepigastrium.

Dysphagia

This problem was identified almost exclusively in severe dorsal kyphoscoliosis and pectus excavatum. It appeared to be related to the interference with chest expansion and changes in position of mediastinal structures produced by the skeletal deformity. These patients all demonstrated significant diminution in the efficiency and capacity of their ventilatory performances.

Liver involvement

The presence of a palpable, tender liver resulting from chronic pulmonary disease was limited to the late stage of cor pulmonale. The basic pathophysiologic finding was passive congestion of the liver due to right heart failure with venous congestion. Abnormal liver chemistries were characteristic of hepatocellular damage.

Hernia

Although it cannot positively be stated that hernia is a direct result of cough, the dynamics of cough with its increasing of the intra-abdominal pressure presents a situation ideal for promoting herniation. The majority of patients with this complication have far-advanced emphysema with markedly flattened, fixed diaphragms and severe, explosive cough.

Diarrhea

The problem of diarrhea was almost always the result of treatment measures (table 2). Previous reports indicate that tuberculosis of the intestinal tract is a frequent, severe complication of pulmonary tuberculosis.¹³ From this information one could expect diarrhea to be a common problem in pulmonary tuberculosis. In our recent experience, however, this has not been the case. As intestinal lesions are prone to occur during the early, active stage of tuberculosis, and rarely before the pulmonary lesion has been discovered, the use of current antituberculosis chemotherapy either diminishes or masks the symptoms of this complication. According to a report from Fitzsimons Army Hospital¹⁴ approxi-

mately 25 per cent of pulmonary tuberculosis patients in sanatoria have clinical or radiologic evidence of intestinal tuberculosis. Intestinal involvement usually occurs in the ileocecal region (85 per cent) because of the affinity of *Mycobacterium tuberculosis* for lymphoid tissue. Spread from the lung may occur by direct extension via swallowing or by hematogenous or lymphatic spread.

Difficult liver biopsy

This problem was encountered only in patients with far-advanced emphysema. In addition to the obvious part played by lung volume inflation, flaring of lower rib cage, and flattened diaphragms in preventing the needle from reaching the liver, atrophy and fibrotic contracture of the liver may have been present. The four patients in whom liver tissue could not be obtained had been diagnosed as having Laennec's cirrhosis.

Dehiscence (postoperative)

This complication arose in patients with chronic bronchitis and emphysema who postoperatively had pneumonia with severe, explosive cough. The complication appeared to be directly related to the severity and dynamics of the cough.

Trachea-esophageal fistula

This complication arose in a 56-year-old white man with advanced metastatic squamous cell carcinoma of the lung.

GASTRO-INTESTINAL PROBLEMS FROM TREATMENT OF CHRONIC PULMONARY DISEASE

Tables 2 and 3 summarize the frequency distribution and nature of gastro-intestinal problems arising as complications of treatment. The triad of anorexia, nausea, and vomiting was by far the most frequent and bothersome. There is little more in the way of detail that need be added to the information provided in the charts.

Recently a large number of outpatients were given short, periodic courses of wide-spectrum antibiotics (aureomycin (brand of chlortetracycline hydrochloride) and terramycin (brand of oxytetracycline)) in the management of intercurrent infections complicating such chronic states as emphysema, bronchitis, bronchiectasis, and fibrosis. To my knowledge only two or three of the total have had complications necessitating change or interruption of therapy. The usual schedule consisted of 250 mg of terramycin or aureomycin 4 times daily for 3 to 6 days. This schedule does not appear to carry the morbidity noted in heavy dosage schedules used for more acute, toxic infectious diseases.^{2,3} Usually the problems can be controlled by having the patient take the medication with buttermilk immediately after meals.

TABLE 3. *Procedures and drugs causing gastro-intestinal problems in the management of chronic pulmonary disease*

Treatment	Problems encountered
Antibiotics	
Terramycin hydrochloride	Nausea, vomiting, diarrhea, anorexia, abdominal pain, vitamin B deficiency
Aureomycin hydrochloride	Anorexia, nausea, vomiting, diarrhea, abdominal pain, proctitis
Aerosol penicillin	Stomatitis, esophagitis, hairy tongue
Oxygen via nasal catheter	Stomatitis-pharyngitis-esophagitis (dysphagia)
Pam-aminosalicylic acid	Anorexia, nausea, vomiting, abdominal pain
Triton (brand of alkyl aryl polyether alcohol) aerosol	Stomatitis-pharyngitis (dysphagia)
Aminophylline (orally)	Anorexia, nausea, abdominal pain
Potassium iodide	Anorexia, nausea
Elixir terpin hydrate and codeine	Nausea, vomiting, abdominal pain
Pneumoperitoneum	Anorexia, abdominal pain, constipation

The intra-abdominal complications and sequelae of pneumoperitoneum represented in this series have been limited and with no serious consequences. A recent report indicates an over-all incidence of significant complications of about 1 per cent.¹⁴ Pneumoperitoneum has been definitely incriminated as contributing to the death of two patients.¹⁴ Several patients were reported to have developed low-grade peritonitis with dynamic small-bowel obstruction. Reports in the literature describing accidents incurred as a direct result of air instillation include: (1) air embolism, (2) spontaneous pneumothorax, (3) inflation of hernial sacs, and (4) perforation of hollow or solid abdominal viscera. The use of pneumoperitoneum as treatment of far-advanced emphysema has been disappointing because of numerous complaints, usually from elderly patients, regarding such symptoms as: (1) tight abdominal fullness, (2) crampy pains, (3) anorexia, (4) diarrhea or constipation, and (5) inability to eat a full meal.

The appearance of vitamin B deficiency in three elderly men who were on antibiotic therapy was very striking. Stomatitis, cheilosis, atrophy of tongue papillae with magenta color, and dysphagia were the presenting problems. High vitamin B therapy

SERVICE ARTICLES

PROGRAM FOR MEDICAL PREPAREDNESS

MAJOR GENERAL SILAS B. HAYS

Surgeon General, U. S. Army

EACH OF THE four Surgeons General since 1939—Magee, Kirk, Bliss, and Armstrong—has served at least part of his term during a period of combat. I sincerely hope that my term will be wholly one of peace. Nevertheless, much of our effort in the immediate future must be devoted to problems of war. The radical changes in concepts and doctrine of war brought about by the development of nuclear weapons make it imperative that we modernize and improve our medical preparedness. The tasks we face are both essential and difficult. Their accomplishment will require a degree of enthusiasm and effort on the part of all concerned that is more characteristic of war than peace.

In facing these problems I am fortunate in having a capable and enthusiastic staff. With their help I have outlined a program which we believe will best accomplish the mission of the Army Medical Service. I want to present this program publicly so that interested persons within and without the Army can assess it, and by expressing their concurrences or differences help translate it into a practical plan of action. I chose this particular occasion to present my views because I know that you, experienced and interested in both military and civilian medicine, are best equipped and motivated to evaluate the program. I am confident that from you will come the frank constructive criticism that this broad program must have before it can be ironed into specific objectives and policies.

My talk today is oriented toward *medical* problems almost exclusively. At a future date it is my hope that similar statements will be made concerning problems and programs of the other components of the Army Medical Service.

MISSION OF THE ARMY MEDICAL SERVICE

The primary mission of the Army in peacetime is preparation for war. The Army Medical Service, as an integral part of the Army, must never lose sight of *its* role in accomplishing this mission. At the same time, as a supporting service, it has the equally important mission of maintaining and conserving the health of the Army during peace. I do not view these as separate

Presented to the Society of Medical Consultants to the Armed Forces, 21 November 1955.

missions but rather as one integrated whole. It is difficult for me to visualize an improvement in the care of the peacetime soldier that does not improve our ability to perform our wartime mission. Furthermore, to the extent that we fail to keep the peacetime soldier in the best possible health, to that extent we make the Army's task of preparing for combat more difficult.

MEANS OF ACCOMPLISHMENT

We in the Army Medical Service utilize three basic instrumentalities in performing our mission of conserving the fighting strength: first, selection, elimination, and classification of personnel; second, the practice of preventive medicine; and third, the practice of therapeutic medicine.

MANPOWER

In a major war, manpower will be the Nation's most critical resource, and every person, able-bodied or handicapped, must be utilized. An appreciable part of this program is entrusted to our stewardship. Although personnel selection, elimination, and classification do not have the humanitarian aspects associated with the care of the sick and wounded, our efforts in this area can do much to maintain an efficient, fighting Army. We establish physical and mental standards for induction and separation. If we set our standards too high, we eliminate many persons who could render satisfactory service. If we set them too low, we saddle the Army with noneffectives. If we do not assist in the classification of personnel, handicapped and ineffective persons will be assigned to jobs beyond their capabilities, and able-bodied men to the jobs which require lesser capabilities.

We have learned much from our experience in World War II and more recently, the Korean conflict. However, I believe that we have as yet not fully exploited our experiences. The time has come to test and to approve or discard such programs is now and during mobilization. The area on which we intend to place particular emphasis is classification of personnel—the matching of capabilities of the individual person with requirements of the jobs to be performed in the Army. It is essential that we classify the physical, emotional, and mental qualifications of the person and the corresponding requirements of the job in a manner to facilitate proper assignments in the Army.

PREVENTIVE MEDICINE

The second instrumentality, preventive medicine—and I include preventive psychiatry in this term—has proved its value. For many years we in the Army have been leaders in this field and our efforts have paid off not only in the health of our troops but in the health of the whole Nation. When applied to prevent

medicine, the old adage, "a penny saved is a penny earned," should be changed to "a penny saved is two pennies earned"; for each soldier kept out of the medical stream, another who would be required to care for him is freed for nonmedical duties. We do not intend to let the Army Medical Service rest on past laurels in this field. Current projects which show promise will be continued and I hope brought to successful conclusion. Remaining problems of preventive medicine will be sought out and studied.

The Army is now in one of the healthiest periods of its history. The noneffective rate exclusive of battle casualties, which is the most meaningful index of health in the Army, dropped from 20.2 per 1,000 strength per year in fiscal year 1953 to 15.8 in 1954 and 13.6 in 1955. However, our most recent data indicate that the noneffective rate is leveling off.

Despite recent advances, acute respiratory infections remain the major cause for admission of military personnel to hospitals and quarters. Incidence rates for acute respiratory infections have been higher at installations engaged in basic training than at other Army posts. Last winter the incidence rate for common respiratory infections and influenza at installations training recruits was almost two and one-half times as high as at posts with seasoned troops; the incidence rate for pneumonia was more than five times as high. Encouraging progress has been made—much of it here at Walter Reed Army Institute of Research—particularly concerning the cause of certain acute respiratory infections. However, much remains to be accomplished.

The prevention of injuries is another problem which requires attention. Admissions for injuries constitute only about a tenth of total nonbattle admissions to hospitals and quarters, but they account for one fifth of man-days lost and over two thirds of nonbattle deaths in the Army. Within the Army the primary responsibility for accident prevention is placed on G-1. There are, however, definite medical implications in the field of safety which we cannot shirk. In an endeavor to reduce the number of accidents, the Army has sponsored the Accidental Trauma Commission of the Armed Forces Epidemiological Board in several different projects. Studies are underway to determine, if possible, such things as accident proneness and psychiatric, psychologic, and social traits relating to personnel often involved in accidents.

Our over-all approach to psychiatric problems in the Army has shifted heavily to its preventive aspects. During World War II we learned many lessons and developed many policies and procedures which, when applied in the Korean conflict, resulted in a very appreciable saving of manpower. Not only were psy-

chiatric admission rates lowered, but so also were separations from the service for psychiatric reasons.

During the current state of peace, mental hygiene consultation services, division neuropsychiatric service, and other outpatient psychiatric services continue as the mainstay of psychiatric prevention and therapy. The effectiveness of our mental hygiene consultation service is reflected in the large percentage of persons returned to duty. Of 25,000 patients treated for psychiatric conditions last year, over 68 per cent were returned to duty; 26 per cent were recommended for discharge, mostly through administrative channels; and less than 6 per cent were referred to hospitals. Favorable results are also noted in the sharp decrease in both open and closed ward hospitalization rates for neuropsychiatric disorders and in lower separation rates. Currently these services are limited generally to posts of 18,000 strength or more. It is important to extend this approach to oversea areas and to smaller posts in the United States.

The principles of management of combat psychiatric casualties are almost deceptively simple, yet experience has shown that time and again the lessons of the past have been forgotten. One of the principal reasons for this has been the loss or dilution of the trained career officers in the interim between conflicts with a resultant lack of perpetuation of lessons learned. Nuclear war poses new problems in military psychiatry. In a mass casualty situation every physician will have to be a surgeon, and he will also have to be a psychiatrist. It is our intent to see that the principles of preventive psychiatry are fully emphasized and implemented, and that all medical officers receive some training in military psychiatry with particular emphasis on the problems of mass casualties.

Preventive medicine in the Army was originally concerned almost exclusively with prevention of infectious diseases and recent wars have stimulated concentration on preventive psychiatry. The concept of preventive medicine, however, is broader than this. In recent years civilian medicine, particularly industrial medicine, has made strides in considering the individual in relation to his job, keeping him fit for duty and at work. This requires study of both the man and the job. Leaders of industry have found that this approach, although it costs money, pays cold-cash dividends in higher production. I am convinced that we in the Army have a fertile field here which we have not cultivated sufficiently.

THERAPEUTIC MEDICINE

Our third instrumentality is the practice of therapeutic medicine and surgery in patient care. Our reputé in the Army and in civilian medicine hinges largely on the quality of this care.

The Army Medical Service is proud of the high quality of professional care it renders. One concrete evidence of the standard of patient care in the Army is that out of 40 Army hospitals considered by the Joint Accreditation Committee, 39 have been fully accredited, one provisionally accredited, and none rejected. Today, reference to "medicine as practiced in the Army" is a compliment.

The quality of patient care is not self-perpetuating, however, particularly in the Army where conditions change frequently and sometimes radically. The over-all quality can be maintained only by achieving an acceptable standard for every factor contributing to it. This brings us to the major problem the Army Medical Service is facing today. The quality of our patient care is being threatened because of an imbalance between workload and resources. We have faced such imbalances in the past, but they were of a temporary nature. The current problem, however, will not disappear of its own accord and is bound to become more acute if left alone. Furthermore, the problem is complex and does not lend itself to a single one-shot solution. This problem has many facets—dependent care, the contraction of the Army, the 3 per 1,000 ratio, inadequate incentives for procurement and retention of medical officers, and the change in professional maturity of our doctors. All of these facets must be analyzed and thoroughly understood if a proper solution is to be found.

I have already mentioned the striking reduction in the non-effective rate of Army personnel. This favorable situation is at least partially due to the strong emphasis placed on outpatient care in recent years. It has not only helped reduce hospital admission rates but has contributed to the reduction of the duration of stay of hospital patients. This trend, in combination with the contraction of the Army and the elimination of the few remaining battle casualties from our hospitals, has resulted in a sharp drop in the total volume of patient care for active duty Army personnel. The inpatient load, measured by occupied beds, for active duty Army personnel in 1955 was only half of that in 1953, and even the outpatient load showed some reduction.

I would now like to contrast this experience with the trend in patient workload for families of military personnel. The number of dependents occupying beds in Army hospitals has not decreased, and the number receiving outpatient care has increased by more than one third in the last two years. There are a number of reasons for this increase. One is the tendency toward earlier marriages. The Army has changed from an organization of bachelors to an organization of married men. The most important factor, however, is availability of housing. The dependent

workload varies more with the availability of housing than with troop strength. Family housing on and near military posts is increasing. The net result is that care for military families has increased from a relatively small factor to one fifth of inpatients and one third of outpatients in Army facilities. In actual workload it is an even larger factor. The greater part of family care is in obstetrics and pediatrics, and these patients require considerably more of the physician's time than the average military patient. It is my estimate that 40 per cent of the time of medical officers engaged in patient care is concerned with families. Under the cross-servicing policy, personnel of the Navy and Air Force receive medical care in Army facilities and Army personnel are provided care in Navy and Air Force facilities. In terms of workload, we are in approximate balance with the Navy, but more Air Force personnel receive care in Army facilities than Army personnel in Air Force facilities.

The turnover rate of patients is an important factor due to the volume of work generated on admission and disposition. The length of patient stay in Army hospitals has decreased over 20 per cent in the last two years, requiring more of the physician's time per patient day.

Another important factor is that the size of Army hospitals in operation has decreased markedly. The average size of Army hospitals in the United States is now only two thirds of what it was in May 1953 when the ratio ceiling for medical officers was imposed. This is a direct result of reduced troop strength, the drop in hospital admissions, and the reduction in duration of hospital stay. The smaller the hospital, the more expensive the operation, not only dollarwise but also doctorwise.

OTHER RESPONSIBILITIES

The Army Medical Service has many varied responsibilities other than patient care. These responsibilities—research, training, advisory missions to foreign nations, mobilization planning, staff and command responsibilities—have not decreased, and some have increased in recent years. As one example, over 11 per cent of our medical officers in continental United States are currently involved in a large maneuver in Louisiana called operation Sage Brush. Most of these responsibilities are not related to the size of the Army but rather to its mission and deployment. These responsibilities are integral to the Army's basic mission of preparation for war as well as to the maintenance of a high standard of medical care during both war and peace.

THE WORKLOAD

Nevertheless, the Army is operating under a Medical Corps ceiling related to size of the active Army, and size of the active

Army alone. This ceiling of three medical officers per 1,000 active duty strength was barely adequate at the time it was imposed in May 1953 when the strength of the Army was over one and one-half million; it is inadequate to meet satisfactorily the minimum requirements of the Army under current conditions.

Long before the imposition of ratio ceilings on medical officer strengths, the Army had reduced medical officer utilization radically. As you know, before and during World War II, the Army utilized 5.5 and more medical officers per 1,000 strength. During demobilization when the strength of the Army dropped but battle casualties remained, the ratio rose to approximately 7.5 per 1,000. During the Korean conflict when about 15 per cent of total Army troop strength was engaged in Korea, the over-all ratio was 3.3 medical officers per 1,000 strength. Post-Korea reductions in troop strength raised this ratio only slightly, and it was *immediately brought down by further tightening of belts*. However, everything has its breaking point. The number of medical officers in training, research, and other essential military medical functions has already been reduced to a level which I believe is less than satisfactory. The noneffective rate has been leveling off so that it is unreasonable to expect any substantial further reduction. These factors cannot be expected to produce further savings to counteract the effects on the doctor ratio of reductions in the size of the Army and the increased family population.

At many posts the situation is already critical, and our high standards of professional care are jeopardized. This is manifested by the short time allotted to individual patients. Many medical officers can allow only 5 to 10 minutes per outpatient, with attendant possibility of missed diagnoses. Appointments for consultations frequently are distressingly delayed. The waiting time in outpatient clinics is excessive. Medical histories become all too brief, incomplete, and lacking in pertinent detail. Progress notes become infrequent, irregular, and incomplete. Medical officers are working long hours without leave; many work 70 or more hours per week. One cannot work at a "continuous sprint" without dire results. The number of official complaints from patients has risen. This imbalance of workload and resources cannot be allowed to continue.

The imbalance can be corrected only by reducing the workload or increasing the relative number of doctors or both. Possibilities of substantially reducing the *military* workload further is out of the question. As you know, a bill is before Congress to provide medical care for military families in civilian facilities, partially at Government expense. In the last couple of years several plans for care of military families have been evolved but all have been controversial, and at this time we have no

way of knowing just what kind of legislation, if any, the Congress will enact.

As I stated at the outset, we must constantly be prepared to support combat. If during peacetime the care of families becomes our *major* workload, it cannot help but de-emphasize our preparedness efforts. It is my hope that the Congress will pass legislation that will assure good medical care of Army families and provide for an effective distribution of this workload between military and civilian resources.

Aside from the humanitarian and professional aspects of the problem, family care is an essential factor in the morale of troops and, therefore, basic to the accomplishment of the Army mission. Medical officers, being both doctors and soldiers, will stretch their capabilities and endurance to the limit before they will deny service to a dependent requiring medical care. Provision of medical care to families is by force of circumstances being tightened up throughout the Army, but it cannot be eliminated nor can it be substantially reduced until other adequate provision is made for such care.

I have been discussing workload; now what about our personnel resources? At present only 35 per cent of our medical officers on active duty are in the Regular Army. Since July 1953, when the ban on resignations was removed, 459 medical officers have resigned, of whom 93 per cent had participated in our residency training program. Our losses by resignation included 184 board-certified officers. This represents a tremendous loss of skilled manpower—skilled not only in professional specialties but also to varying degrees in military competence. Our total losses since July 1953, including resignations, retirements, deaths, and other separations number 553.

Notwithstanding this serious loss of trained medical manpower, we have refused to lower our standards for commissioning in the Regular Army. During this same period we have received 372 applications for commission in the Regular Army Medical Corps. Of these, 58 have been rejected, 63 have either withdrawn their applications or refused their commissions when tendered, 64 are still in process, and 187 have been commissioned in the Regular Army. In brief, our losses since July 1953 have been 553 against gains of only 187, or a net loss in the Regular Army Medical Corps of 366 in this 27-month period. Obviously this situation cannot be allowed to continue if we are to have an Army Medical Service.

CAREER INCENTIVE

It has become obvious to all three military departments that radical action must be taken, and taken soon, to increase attrac-

tiveness for the medical officer career. The Secretary of Defense in June appointed a "Task Force Organization to Explore Problem of Attracting Career Medical and Dental Officers." The findings and conclusions of the Task Force have been discussed. Specific programs for implementing the recommendations of the Task Force are being developed. We will do everything within our power to assist in the development of these programs and their implementation in the shortest time possible.

Direct increase in pay requires Congressional action. Increased pay through promotion in rank is, to a considerable degree, within the authority of the three military departments. Within the last month, we have secured approval for increased promotions in the Army Medical and Dental Corps. These approved promotions are now being implemented, and I am sure this will result in improvement both in recruitment and retention of Army medical and dental officers. The Task Force recommended that the doctor ratio be increased from the current 3.0 to 3.4 per 1,000 strength. Implementation of this recommendation would not only improve attractiveness of an Army career in the Medical Corps but would be the most direct and immediate means of enabling us to accomplish our varied and important missions. No definitive action has as yet been taken on this recommendation.

Congress, in extending the Doctor Draft Act until 1 July 1957, made two changes in the Law. First, it lowered the maximum age from 50 to 45; and second, it exempted those over 35 who had previously been rejected for commission because of physical disability. Based on preliminary surveys, it is estimated that there probably are a sufficient number of doctors in the eligible pool to meet our requirements through 1 July 1957 when the law expires. However, in May or June of 1957, it may be necessary to go into the Priority IV group. In this group are certain individuals who have had very short tours of active duty. For example, there are approximately 500 who have had less than 6 months of service, and 750 more who have had between 6 months and 12 months of service. The increase of the ratio from 3.0 to 3.4 would mean the calling up of something less than 1,000 additional physicians for all three services.

The problem is basically an imbalance between workload and personnel resources. On the workload side, the only possibility I see of reduction is some form of dependent care legislation; on the personnel resources side the only solution is an increase in the ratio. The first requires congressional action, the second is a matter of action of the Secretary of Defense and higher authority. The actual solution may be a combination of both. The long-range solution, however, must lie in a strengthening

of the Regular Army Medical Corps, with the concomitant necessity of calling up fewer two-year men.

With the expiration of the Doctor Draft a year and a half from now, the only doctors available for service will be those liable under the regular draft. In the hope that appreciable numbers of this group could have some degree of residency training, Doctor Frank B. Berry, Assistant Secretary of Defense (Health and Medical), developed his plan for deferment of individuals for the current and the next fiscal years. The numbers which are being deferred under this plan are not sufficient, in my opinion, to make available to us the professional competence which will be required.

The employment of civilian physicians is being exploited, even though this can help to solve only a part of our shortage problem. Recent increases in salary levels and more concerted recruitment have increased the number employed to 300 full-time equivalents. This actually represents a far greater number of civilian doctors utilized on a part-time basis. We hope to increase the number and the quality employed.

The impending shortage of specialists in the Army puts additional emphasis on our professional training program for the future. The most important factor in the high standard of our patient care in recent years is the increased professional competence of our military medical officers. The value of sound professional training programs emphasized by Kirk, Bliss, and Armstrong has been proved in dividends to our patients, to our doctors, and to the Army Medical Service. Our present professional training programs are geared to accomplish several purposes: to provide for our officers opportunities for continuity of training and education; to create for them programs by which they can acquire specialist training and keep abreast of recent medical advances; to maintain the high quality of medical care in the Army; and to attract career Medical Corps officers. I propose to retain these objectives.

TRAINING PROGRAMS

In order to accomplish these objectives we have placed major emphasis not only on our residencies and our intern program but also on what we consider an excellent postgraduate education program. I should like to outline briefly for you these programs and some of the problems associated with them.

Our residency program now covers 22 specialties. Residencies are being conducted at four of our major teaching hospitals in this country—Walter Reed, Brooke, Fitzsimons, and Letterman—and at Tripler in Hawaii. Internship programs are conducted at these, and at Valley Forge, Madigan, and Beaumont. Oppor-

tunities for residency training are afforded only to Regular Army officers. Although it is true that a Regular officer may resign from the service upon completion of his obligatory service, we hope that additional incentives will result in an increasing number electing to make the Army their career. The success of our residents in obtaining board certification has been most gratifying.

Like most teaching hospitals, we are oversubscribed in certain specialties and undersubscribed in others. The question is frequently raised as to whether or not our residency training in the specialties should be opened to Reserve officers. Recently we submitted to the Department of Defense a proposal to admit Reserve officers to our programs with the proviso that they be required to pay back an extra year above that required of the Regular officer. The proposal is currently under consideration in the Office of the Secretary of Defense. I think you will be interested to know, too, that on 1 September we started a two-year general practice residency at the U. S. Army Hospital, Fort Knox, for Reserve officers.

The Army Internship Program has proved to be an increasingly attractive one. Our primary objective in establishing this program, of course, is to interest these interns in a career as a Regular Army Medical Corps officer. That the program has succeeded only to a moderate degree in this respect is evidenced by the fact that only 44 out of 149 interns in our last class have been approved for commission in the Regular Army. We must do a better job of selecting interns who are motivated for the Army and a better job of selling them on the Army while they are interns.

Other postgraduate training for Medical Corps officers functions in two forms—the in-service short course program and the civilian institution program. Our teaching hospitals have always taken great pride in conducting such courses as the Kinbrough Urological Seminar, Symposium on Pulmonary Diseases, Recent Advances in Internal Medicine, Obstetrics and Gynecology Seminar, and many others. These courses have proved popular not only among service officers but to many civilian physicians as well.

The civilian institution program was created to provide training at universities throughout the country that could not otherwise be obtained by in-service courses. Last year, 59 medical officers received training in civilian institutions in courses varying from two days to 12 months.

HOSPITAL FACILITIES

The quality of medical care can be maintained only by achieving an acceptable standard for every factor contributing to it.

One of the weak links in this chain has been the physical inadequacy of our hospital plants to meet the requirements of modern efficient hospital operation. Many of our hospitals are not only in poor physical condition but were designed for a size and type operation which is radically different from the current situation. A replacement program for hospital facilities is necessary and has been started. The first increment was authorized in 1952 when funds were appropriated for seven permanent type hospitals. An example of the type of structure is the 500-bed hospital on a 1,000-bed chassis. Six hospitals are now under construction—at Fort Knox, Fort Belvoir, Fort Bragg, Fort Benning, Fort Riley, and Fort Monmouth. The seventh hospital, at Fort Dix, is still in the design stage.

Additional hospitals were authorized and funds appropriated in the 1956 Public Works Program. These hospitals are at Fort Leavenworth and Fort Jackson. It is contemplated that two additional hospitals, at Fort Meade and Fort Ord, will be included in the fiscal year 1957 Public Works Program. These projects are now being considered by the Department of Defense. At last we can say that a progressive construction program is under way.

MEDICAL STAFF PROBLEMS

I should now like to discuss problems more directly related to our preparedness mission. The probability of employment of atomic weapons in any future major conflict requires that we re-examine the organization and doctrine of medical service in the field. In fact, the Chief of Staff has directed that such studies be undertaken with the view to improving the combat potential of the Army. In part, these studies have been pointed toward the determination of the type of support units and the optimum ratio of such units to combat units required to win a two-sided atomic war.

As a result of these studies, a new command and staff structure of the Army in the field is under development and being tested in maneuvers. I am particularly anxious to see that the position of staff surgeons is in consonance with provision of an effective medical service. If surgeons, as special staff officers, are not immediately available to the major tactical commander, but separated by an intermediate headquarters, then medical matters must go through the intermediate headquarters with resultant modification and delay. Delay in medical matters can prove costly in terms of patient care and lives. Regardless of changes in organizational or functional concepts, the mission of the Army Medical Service "to conserve the fighting strength" will remain unchanged, and we must make sure that the Army Medical Service in the field is organized in a manner to best facilitate effective accomplishment of this mission.

We must re-examine the functions, structure, and composition of our medical units to assure their suitability to meet conditions of modern warfare. We may have to modify some and, perhaps, create new ones. This is a task that will require effort to assure that we come up with the best answers and do it as soon as possible. Be assured that we are working on these problems. We have established a Medical Service Combat Development Board for the testing of field equipment and have re-established the Medical Service Board to work on long-range problems of organization and operation of the Medical Service.

With the expansion of Army aviation we must place increased emphasis on Army aviation medicine. We are now training aviation medical officers and assigning them to headquarters of divisions, corps, and armies, to certain major aviation battalions and groups, and on an area basis. This training is primarily in the Air Force School of Aviation Medicine at Randolph Air Force Base.

We must also re-examine the doctrine and, perhaps, organization of medical service support beyond the immediate theater of operations. We must do this with a view toward possible commitment in a local or limited conflict such as in Korea as well as preparedness for total mobilization. We must take into consideration not only the new weapons but the higher mobility of the Army, the increased speed of patient evacuation and similar factors. Experience with air evacuation in Korea has taught us that the continental United States hospital system must be prepared for much more rapid expansion during the first stages of conflict, and must be more sensitive to fluctuations in casualty rates than was required previously. Each aspect of preparedness must be re-examined in light of current thinking, and plans must be adjusted accordingly.

We must, of course, continually re-examine our training programs to assure that they reflect the latest doctrine and concepts of modern warfare. All our training and educational activities must include the military aspects of medicine. In our residency program we are now setting aside one hour a month for the purpose of conducting a conference on military medicine. We require, too, that a Medical Corps officer located at each teaching hospital, who has the proper military background and experience, be designated as the co-ordinator of military medicine and that he be given the responsibility for this program. The application of military medicine is being stressed on all teaching rounds.

MASS CASUALTIES

In keeping with our responsibilities for national preparedness, we are putting considerable stress on the handling of mass cas-

ualties. One of our courses, "Medical Care of Atomic Casualties," has become so well known to all the military services, as well as to such other agencies as the American Medical Association, the Public Health Service, the Federal Civil Defense Association, the National League for Nursing, the American Hospital Association, and other groups, that we have had to increase our quotas from an original 32 participants to 100, and from 4 courses a year to 6.

Another course of this type which was developed and conducted for the first time last year is "Surgery in Acute Trauma." This course, or rather series of courses, was conducted at all of our teaching hospitals. The scope and content of these courses include early management and transportation of wounded, a review of types of wounds, débridement, shock, problems in the administration of blood and blood derivatives, acute renal insufficiency in war casualties, perineal wounds, peripheral blood vessel injuries, and many other aspects of acute trauma.

Both the Army Medical Service School and the Walter Reed Army Institute of Research, as well as our hospitals, conduct a large number of courses for Medical Corps officers that are particularly designed to cover aspects of medicine applicable to national preparedness. I intend that we continue and expand our teaching programs in this direction and that we put increased emphasis on teaching the technics to be used in the care of mass casualties, not only to medical officers, but to dental officers, nurses, Medical Service Corps officers, and medical enlisted men.

In a nuclear war, medical personnel will not be available in sufficient numbers to administer emergency medical aid to the large numbers of casualties, and this task must, in many instances, be performed by nonmedical personnel. Limiting mortality and maintaining unit fighting strength must become a primary element of training for nonmedical military personnel and should be reflected accordingly in training programs of the Army.

We have asked that the period devoted to medical problems be increased from 5 to 22 hours in the soldier's 16 weeks' basic military training. The Department of the Army has concurred in this plan in principle but finds difficulty in adjusting the basic training program to allocate the required time. Regardless of how many hours are finally allocated to medical subjects, we intend that each soldier, in the absence of medical service advice and supervision, be able to administer self-aid or first aid as it pertains to the control of hemorrhage; prevention and treatment of shock; positioning and treatment of fractures; care and treatment of open wounds; treatment of burns; artificial respiration; positioning of casualties with wounds of the chest,

head, neck, spine, and extremities; and have a working knowledge of sorting and transporting casualties.

RESEARCH

During peace, we must conduct research that will better prepare us to meet our responsibilities in war. We must not lose sight, however, that our responsibilities in war go far beyond front-line medicine. Our program must be broad in scope, involving both basic and applied research in fields which are immediately or reasonably related to the mission of the Army Medical Service. Needless to say, much of this research results in information which is as valuable and applicable to civilian medicine as to military medicine, just as much of civilian medical research has helped to improve the practice of medicine in the Army.

To conduct this research we have several installations which are specifically staffed and equipped. We also support clinical research at most of the named Army hospitals and the Army Area Laboratories and encourage such research at station hospitals where competent and interested personnel are available. We also support a rather large research program through some 380 contracts with universities and civilian hospitals covering 32 major areas. Much of our research is being directed toward four major causes of loss of military manpower. In the area of trauma the more important investigations are directed toward blood and fluid replacement, improved burn therapy, blood volume expanders, improved anesthesia, and vascular prostheses. In the area of communicable disease we are particularly concerned with respiratory disease, infectious hepatitis, enteric disease, virus and rickettsial disease, and immunization methods. As to radiation exposure, we are investigating biological dosimetry and radiation injury. Our research in psychiatric disorders is exploring the problems of stress, rapid treatment methods, and behavior problems. I believe that we have an effective research program. It will be continually evaluated to eliminate projects which are not important to military medicine and to emphasize projects in which the Army has a vital interest.

MEDICAL INTELLIGENCE

Our medical intelligence activities have broadened in scope and may have to be broadened still further. We cannot afford to continue to limit our medical intelligence efforts to preventive medicine aspects of military operations in foreign areas. Our responsibilities in the activities of the North Atlantic Treaty Organization, Southeast Asia Treaty Organization, and Inter-American affairs have placed on us the burden of becoming familiar with all phases of governmental and private medical

administration, practice, research, and training, as well as health and sanitary conditions in these countries. It is only through understanding a country's capabilities that we can assess the manner in which we can best help it or how it can best help us in our mutual defense efforts.

SUPPLY

Medical supply is an important factor in maintaining a high standard of medical care in both peace and war. For the first time we have a sizable reserve of supplies and equipment, valued at 97 million dollars, to lessen the impact of mobilization requirements. The major problem in the medical supply field at present is organizational. Despite the tremendous progress made in unifying medical supply operations of the three services, some proposals recently have been made which would, I believe, separate the control of medical supplies from the doctor, something which I consider neither desirable nor feasible, and which I will continue to oppose.

PROGRAM FOR MEDICAL RESERVE UNITS

The medical reserve program is in need of rejuvenation. Reserve medical units are the muscle of our preparedness. Of a total of 247 authorized Army Medical Reserve Units, only 186 are on an active status. Of the major units, however, 8 out of 9 hospital centers, 5 out of 7 convalescent centers, and all 60 of the general hospitals are currently active. Of the Table of Organization and Equipment (T/O&E) strength, only 42 per cent of medical officers, 30 per cent of total officers, and 9 per cent of enlisted are on the rolls.

There are about 4,500 Medical Corps officers in the Reserve components today, not including those on active duty. Of these, about 3,700 are in the Ready Reserve, but only about 1,400 are participating in training activities.

The new Reserve Forces Act of 1955 has teeth only for the individuals appointed under age 26 and after 10 August 1955. Others can participate or not as they choose. Unless excused under Department of Defense regulations (which by the way are still being staffed) individuals in the Ready Reserve each year must serve two weeks of active duty plus 48 drill or training periods or alternately 30 days of active duty.

Our office has recommended that the regulations being processed contain the following statement: "Such an individual who is practicing a profession—for example, medicine—in which he will be using substantially the same skills in civilian life as he would be called upon to use in the military service may be permitted to participate to whatever lesser extent is

considered by the military department concerned to be necessary to maintain his military proficiency." If this is approved for inclusion in the Department of Defense regulations, we will recommend that the implementing regulations of the Department of the Army require a minimum of 15 drill periods per year plus two weeks of active duty for the professional complements of hospital units.

RESERVE CORPS RECRUITMENT

I have discussed at length the problems of recruitment and retention in the Regular Corps. These problems are just as serious in the Reserve Corps. They do not seem as acute because the reserve components do not face the day-to-day problems of operation of a medical service nor care of the sick. Much of the personnel in both organizations is obtained through compulsion. For doctors, the immediate financial inducements of membership in the reserve are zero. Usually reserve activity means the doctor loses money even though he draws military pay for the time spent. The long-range financial inducement of retirement pay is, I believe, a definite factor in many cases, although probably more in the retention of men with considerable service rather than recruitment of new blood. The other inducement is patriotism or a sense of duty as a citizen. I believe that many doctors today sincerely consider that, in a major war, they can discharge their duty as citizens as well in civil defense activities as in a military unit. Furthermore, in peacetime civil defense requires very little time, and in wartime it probably means service in or near the individual's home community. This situation means tough competition for recruitment of doctors in the Reserve.

What can be done to put new life in our Reserve Program? First, I believe we should emphasize to the young man that during the compulsory period of Reserve Service, the officer can make a good start toward qualifying for retirement pay. We should do everything we can to ensure that the regulations that are promulgated provide that doctors of the professional complement of units do not have to attend the full 48 drill periods in order to be participating members of the units. Our Reserve Training Programs must be revitalized to emphasize those things which are important in *military* medicine, and yet are professionally oriented to capture the interest and enthusiasm of the doctor who is largely wrapped up in the practice of *civilian* medicine. Military surgery and the handling of mass casualties must be stressed as well as preventive medicine and psychiatry. In the last two years we have already made a start in this direction—but we must push further.

We should diversify our summer unit training. Recently, I have observed various types from the strictly tactical type of field training to the strictly clinical type of training in one of our large hospitals. I am convinced that each of our units should have a different type of training each summer, preferably at different locations. This will provide broader training and will stimulate interest. Recently, one of our Reserve general hospitals has requested that it do 30 days of active-duty training next summer in Germany. This suggestion is intriguing, and our office is going to give it careful study. In this day of air travel, I believe we should seriously explore the possibility of using large government transport planes to move, for example, a Massachusetts unit to Texas for two weeks' active duty, or a Texas unit to Colorado.

Recently, additional equipment for reserve medical units has been approved. We will push to see that it is issued during this and the next fiscal year.

The "Michigan Plan" has just been approved for a one-year trial in that state. This provides that general hospitals located in towns which are not large enough to completely support the unit may have satellite fragment units in adjacent localities. We shall watch this experiment with interest.

I should appreciate additional ideas and suggestions for revitalizing our Reserve Program.

CIVIL DEFENSE

I would like to mention our responsibilities with regard to civil defense. I personally believe that clarification of the role of the Army Medical Service in civil defense is one of the major problems requiring solution. Responsibility for civil defense by law is vested primarily in the several states and their political subdivisions. Yet, you will recall that in "Operation Alert" last June, the President promptly "proclaimed" martial law.

We in the Army Medical Service are vitally concerned with the problems of civil defense. We recognize that little distinction can or will be made between military and civilian casualties in the event of a nuclear attack on the United States. The civil defense problem is unsatisfactory in several respects. Fifty thousand casualties, to say nothing of eight million, present a problem taxing the imagination. Who will treat them, and where will they be treated? This involves people, transportation, facilities, and organization. The role of the Army in these areas is uncertain. How will they be treated? This involves medical principles and doctrine, and this is the area on which we are concentrating our work.

Some actions which have been taken and which are related to civil defense should be mentioned. We have developed plans at our various installations in the event of disaster or enemy attack, and have integrated these plans with local civil defense plans to the extent possible. I have mentioned previously our teaching programs which are in part directed toward the civil defense problem. We, with the Navy, Air Force, and United States Public Health Service, are sponsoring a "Medical Education for National Defense" program in a number of medical schools for the purpose of instructing medical students in the problems of national defense medicine. At present there are 15 medical schools participating in this program and it is planned that 10 more will be included next year. The Army Medical Service also sponsors a traveling instructional team which appears before medical societies, medical schools, and Army Reserve components teaching the handling of mass casualties.

We have published a technical bulletin on "Early Medical Management of Mass Casualties in Nuclear Warfare," which has been concurred in by both the Air Force and the Navy. It establishes doctrine, policy, and procedures for the early medical management of mass casualties in the medical services of the Armed Forces.

All Army Medical Service officer personnel, except Medical Corps officers, are required to take a 12-hour refresher course in emergency medical treatment. In all our courses in the Medical Service School at San Antonio, Tex., we are emphasizing the handling of mass casualties and the problems of nuclear warfare.

The Army Medical Service has had wide experience in handling casualties. Yet I would emphasize that we have never had any experience with mass casualties as we now conceive them; nor will we, except in a situation when the chips are down. We think we have some of the answers, but we know that there are many we do not have. We have a handful of men working on these problems; we should have 10 times as many.

SUMMARY

In summary, the double task of readjusting to a peacetime operation and improving our preparedness to support the Army either in a conventional or an atomic war presents many difficult problems.

Paramount is the need to rebuild the Regular Army Medical Corps. Without a strong, professionally qualified corps there can be little hope in achieving our objectives. This major problem is in itself composed of many individual problems—pay, promotion, assignment and rotation, prestige, and training—which must be attacked each in turn.

We must solve the family care problem not only to help us balance workload and resources, but to provide the flexibility that we need to direct our attention to the major mission of medical support of the Army in peace and war.

We must re-examine and improve the preparedness of the Army Medical Service in light of modern concepts of war. This involves research, doctrine, training, organization, our reserve program, and civil defense.

We must not overlook the less acute but equally important problems of the Army Medical Service. We must continue a sound construction program. We must improve utilization of manpower in the Army through better selection, elimination, and classification of personnel. We must not only maintain but improve our standards of prevention and treatment of disease and injury.

The program I have outlined is both ambitious and formidable but, considering mission and circumstances, no lesser goals can be established. It is a task that the Army Medical Service can hardly accomplish alone. But we are not alone. Our relationships with civilian medicine have never been better. Since World War II there has been a growing understanding and with it, strengthening of ties between civilian and military medicine. There now exists full appreciation throughout the medical profession, military and civilian, that as integral parts of the profession of medicine we are all working toward the same goal—to bring to the American people the best medical care possible—and that to achieve this goal we must work together. This meeting exemplifies this close relationship and promises continued co-operative effort between civilian and military medicine. With faith in the ability and dedication of the men and women of the Army Medical Service and our compatriots in civilian medicine, I feel confident that our goals will be achieved.

Undoubtedly the greatest stimulus to progress in health care and hospitalization in Korea since its liberation is military medicine. Most physicians of the ROK Armed Forces have a limited private practice. This is true, too, of the physicians in public health jobs. Most of the military physicians are potential fulltime civilian practitioners sooner or later. As they associate with Western-trained physicians in their military capacities, their professional knowledge is furthered and their potential in the practice of modern medicine is increased.

MEDICAL EDUCATION FOR NATIONAL DEFENSE

Progress Report

The MEND Program was described in the October 1955 issue of this *Journal* as a means of supplementing medical curricula with additional information that might contribute to effective service by the medical graduate in time of national emergency. As of 1 January 1956, 10 more medical schools had joined the Program. These are Temple, Maryland, Duke, Louisiana State, Michigan, Pittsburgh, Washington (St. Louis), Kansas, California (Los Angeles), and New York University. In addition to the 25 schools in full affiliation with MEND, 7 other schools are participating without, at this time, receiving any financial assistance.

Activities sponsored by the MEND Committee for the spring semester include the following symposia:

INFECTIOUS DISEASE PROBLEMS

This symposium, to be held at Great Lakes Naval Training Center, Chicago, Ill., on 14-16 February 1956, is designed to bring to the attention of professors of public health, preventive medicine, bacteriology, internal medicine, and pathology the communicable disease problems encountered by the military services. The program will include formal papers, group discussions, and visits to the laboratories of Naval Medical Research Unit No. 4. The Navy is primary sponsor of the symposium, with participation of Army, Air Force, Public Health Service, and medical faculty personnel.

RADIOBIOLOGY

Walter Reed Army Institute of Research, Washington, D. C., will be host to this symposium on 9-11 April 1956. Problems arising from human contact with all types of radiation and radioactive materials will be taken up in papers and panel discussions that will cover acute and chronic aspects of radiation disease from flash burns to genetic effects. Further discussion will be concerned with medical problems expected to appear from increasing use of nuclear reactors in civilian enterprise and in military operations. The Army is primary sponsor, with participation by other agencies of the Government and by faculty members.

Medical officers of the Armed Forces are invited to attend these symposia on a space-available basis. Any officer interested in further details should contact the National Coordinator, MEND Program, Bureau of Medicine and Surgery, Department of the Navy, Washington 25, D. C.

Clinicopathologic Conference

U. S. Naval Hospital, San Diego, Calif.*

MELENA, FEVER, AND PAIN

Summary of Past Clinical History. A 69-year-old retired naval officer was first admitted to the hospital as a medical emergency, having had a sudden episode of hemorrhage from the bowel. He had been retired in 1947 because of glaucoma. On the morning of admission, he vomited blood and passed a black stool. He became quite weak but did not complain of pain. In 1935 the patient had a somewhat similar episode and examination revealed a duodenal ulcer. A gastroenterostomy was performed, and the patient had received no medication since that time.

FIRST ADMISSION

Physical Examination. The patient was a well-nourished, well-developed, co-operative male in no acute distress, but appearing pale and weak. The blood pressure was 112/70 mm Hg; the pulse was 100 per minute. There were no other significant findings except for a hemoglobin of 9.3 g per 100 ml; hematocrit, 30 ml per 100 ml. White blood cell count was 7,000 per μ l with a normal differential. Urinalysis and serologic tests were negative.

Course in Hospital. There was a consistent, daily, intermittent fever. A whole blood transfusion elevated the hemoglobin to 10 g per 100 ml. At no time did he complain of pain and there was no recurrence of vomiting. The black stools persisted for two or three days and then the patient became constipated. Mild laxatives were necessary to relieve the constipation. His febrile course was significant in that every 24 to 48 hours he would have a shaking chill, and the temperature would range to 103° or 104°F and then subside. These febrile episodes were not associated with any pain or distress. Febrile agglutination tests and repeated blood smears for malaria studies were negative. White blood cell count was 17,900 per μ l, with 78 per cent segmented neutrophils, 7 per cent band neutrophils, and 15 per cent

*Rear Adm. Robert M. Gillett (MC) USN, Commanding Officer. From the Pathology Service, Capt. John S. Shaver (MC) USN, Chief.

lymphocytes. Stool examinations were negative for pathogenic protozoa. After approximately six days of chloroquine phosphate therapy, there was no apparent improvement or change in his febrile state, and the patient was given a combination of penicillin and streptomycin sulfate. Blood cultures prior to this antibiotic therapy were consistently negative. Following penicillin and streptomycin sulfate therapy, the patient's fever rapidly subsided and he became afebrile. His immediate course in the hospital was also complicated by intractable hiccoughs which lasted about 10 days.

Gastro-intestinal studies with contrast medium were reported positive for a large duodenal ulcer. Gall bladder studies with intravenous dye revealed a faint gall bladder outline.

The patient's subsequent course of hospitalization was uneventful. He became ambulatory, felt very well, slept well, and was troubled only with a mild intermittent constipation. He was discharged from the hospital in an asymptomatic state to be followed as an outpatient.

PRESENT ADMISSION

The patient was readmitted to the hospital 26 days later complaining of severe pain in the right sternoclavicular joint, fever, excessive sweating, and thirst. The pain was described as being severe, constant, and sometimes "throbbing" in character. His fever began four days prior to his readmission and was associated with drenching night sweats. There was no headache and no other joints were involved.

Physical Examination. The patient was an alert, active, apprehensive white man with a florid complexion and a warm, moist skin. Temperature was 101.8°F; pulse, 110, regular; blood pressure, 120/85 mm Hg. An electrocardiogram revealed only a sinus tachycardia. The cardiac impulse was visible over the whole left chest. Findings of an abdominal examination were not remarkable. There was no edema or vein distension.

Laboratory Studies. At this time the red blood cell count was 3.5 million per μ l; hematocrit, 33 ml per 100 ml; white blood cell count, 10,600 per μ l, with 73 per cent segmented forms, 2 per cent band forms, and 25 per cent lymphocytes. Urinalysis showed 10 mg of albumin in a random sample; blood urea nitrogen was 10.3 mg per 100 ml. Blood cultures were negative. Radiographs of the chest showed a moderate elevation of the right hemidiaphragm with only 66 per cent range of normal excursion. Two large discoid densities were present in the right lung base, one in a posterior position and the other situated anteriorly (fig. 1). A gastro-intestinal roentgenogram and fluoroscopic study showed an "active duodenal ulcer." The gastrojejunostomy was reported as functioning normally (fig. 2).

Figure 1. Roentgenogram of the chest, showing elevation of right hemidiaphragm and two large discoid densities in the right lung base.

Course in Hospital. Treatment consisted of thorazine (brand of chlorpromazine hydrochloride), luminal (brand of phenobarbital), and chloroquine phosphate. The fever, shaking chills, and right shoulder pain continued. On the 10th day of his second hospitalization a bronchoscopic examination showed no abnormal findings except for a moderate mucosal pallor. The abdomen was soft, and no palpable masses were evident on physical examination. A short time after the bronchoscopic procedure, the patient's blood pressure suddenly dropped to 96/48 mm Hg. The pulse rose to 140 per minute, and respiration became shallow with a rate of 40 per minute. The temperature was elevated to 105°F. Physical examination showed dullness, decreased breath sounds, and coarse rales over the right lower lung field with clinical signs of elevation and splinting of the right diaphragm. There were some decreased breath sounds over the left lower lobe, but no rales or dullness to percussion. On the following day re-examination revealed absent breath sounds on the right side of the chest with marked tenderness over the posterior area of the right chest wall. A roentgenogram revealed massive pleural effusion

of the right side with approximately 40 per cent collapse of the right lung. On the evening of the same day, the patient became very dyspneic, lapsed into coma, and died.

Figure 2. Gastro-intestinal roentgenogram, showing an "active duodenal ulcer."

DISCUSSION

Doctor Sheppard:* In view of the history and clinical findings in this case, we must consider the probability that the patient did have a subdiaphragmatic abscess. Presumably, the terminal episode represents a very good possibility of a rupture of a subdiaphragmatic abscess into the right pleural space with a resulting empyema and massive compression pulmonary atelectasis. A chronic duodenal or gastric ulcer with lesser peritoneal cavity adhesions could silently rupture into the upper abdomen and result in a subdiaphragmatic abscess, and could burrow through the right hemidiaphragm to produce a massive purulent effusion into the right pleural space. There are many lesions other than ulcer that could result in an infection in the upper abdominal area and produce the same course of events. A suppurative cholecystitis with rup-

*Lt. Haynes W. Sheppard (MC) USNR, Thoracic Surgery.

ture or infection from the stomach via lymphatic or blood stream could result in a subdiaphragmatic abscess; however, this would be less likely than direct extension from involved viscera. This patient had a gastroenterostomy, in addition to his ulcer, as indicated by radiographs and by the clinical history, and it is quite possible that a marginal ulcer existed with perforation, resulting in a diaphragmatic abscess. Occasionally, a fulminating appendicitis with rupture may extend retroperitoneally into the right subdiaphragmatic space and produce the same clinical picture. One possibility that comes to mind in reference to a thoracic problem that could result in a rapid demise of a patient, as appeared to be the situation in this case, is the spontaneous rupture of the esophagus. However, I think this possibility can be excluded in view of the fact that the mediastinal emphysema usual in such cases was not apparent in this case. Also, ruptures of the esophagus, with the usual complications, are predominantly on the left side rather than in the right pleural space. An acute fulminating pneumonia with effusion could produce symptoms as rapidly as we have here, with sudden demise of the patient. I think that obscure malignancies of the pancreas, stomach, duodenum, or any of the upper abdominal organs with rupture and infection in the retroperitoneal space could well produce symptoms similar to those present in this case. If I were called upon to make definitive diagnosis, based upon clinical history, signs, and symptoms I would say that the patient had a rupture of a duodenal ulcer with formation of a subdiaphragmatic abscess and subsequent perforation of the diaphragm with spilling of the purulent material into the right pleural space. May we look at the roentgenograms?

Doctor Wulfman:* Many radiographs were taken. The gastro-intestinal series made upon the patient's first admission show a functional gastrojejunostomy. The duodenal cap is not filled out, but appears defective. The emptying time of the stomach and duodenum was a little more than five hours. No marginal ulcer is evident at the site of the gastrojejunostomy. A repeat gastro-intestinal series during the latter part of the patient's first admission was done, and we failed to find any lesions except for the defect previously described in the duodenum. On the first day of the patient's second hospitalization, two radiographs of the chest showed elevation and a fuzzy contour of the right diaphragm. This suggests some pleural reaction. Also some atelectasis of the right lower lobe is evident. A portable film made shortly before the patient died shows a paradoxical motion as well as limitation of excursion of the dome of the right diaphragm. Radiographs of the gall bladder with radiopaque dye contributed nothing significant. In conclusion, we were looking for a lesion in the stomach to account for a presumed subdiaphragmatic abscess. Numerous spot films were taken of the upper gastro-intestinal tract, and we are unable to find any lesions other than the defective duodenum, which was known to have been present from the beginning of the patient's illness. Our radiographic impression

*Comdr. William A. Wulfman (MC) USN, Radiology Service.

are: gastrojejunostomy with no associated abnormality; active duodenal ulcer; right subdiaphragmatic abscess with paresis of the diaphragm; massive pleural effusion, right; and compression atelectasis, right lung.

Doctor Davis:* I followed this patient on the ward and would like to add something that might be helpful to the history, which is not quite complete. It was my considered opinion, after examining him, that this patient had a subdiaphragmatic abscess. We entertained all of the possibilities as to the cause of a subdiaphragmatic abscess. Inasmuch as he had had duty in widespread areas of the world, it was believed that amebiasis might constitute a reasonable explanation for the elevated diaphragm and for the septic type of clinical course. Repeated stool examinations were negative for *Endamoeba histolytica*; however, because of the seriousness of his illness, the patient received treatment for amebiasis for six days. This failed to influence the clinical picture. Upon his first admission, our first problem became one of nursing because of intractable hiccoughs. As you know, intractable hiccoughs at this age is usually an ominous symptom, and we were of the opinion that this patient was quite seriously ill for a considerable period of time. He received combined penicillin and streptomycin sulfate therapy for at least two weeks. The hiccoughs ceased, the fever slowly subsided, and the patient became asymptomatic. He was discharged from the hospital because he desired to go to his home and because he felt well. He was seen in the outpatient department once a week and was asymptomatic.

Twenty-six days after discharge from the hospital the patient was readmitted because of shaking chills and a septic type of temperature. This second episode began to develop two days prior to entrance to the hospital. We thought of the possibility of a posterior perforation of his duodenal ulcer. However, in my experience, it is unusual to have a posterior duodenal ulcer rupture without some clinical signs, at least some pain. This patient had no pain and no evidence of abdominal rigidity. Repeated gall bladder studies revealed a functioning organ without evidence of calculi. A diagnosis of acute pyelonephritis with complications was entertained; however, this was excluded as a causative factor in view of the negative pyelograms and urinary studies.

Clinical diagnoses:

1. Duodenal ulcer, perforated
2. Subdiaphragmatic abscess, right
3. Pleural effusion and pulmonary atelectasis

Dr. Sheppard's diagnoses:

1. Chronic duodenal ulcer, perforating type, lesser peritoneal cavity
2. Subdiaphragmatic abscess with perforation of right hemidiaphragm
3. Empyema, right, with compression type pulmonary atelectasis

*Comdr. George M. Davis, Jr. (MC) USN, Medical Service.

PATHOLOGIC FINDINGS

Doctor Bench:* At autopsy, 1,000 ml of thick, purulent exudate was found in the right pleural cavity. The right lung was collapsed and covered by a similar fibrinopurulent material. No abscesses or areas of consolidation were evident in the lung parenchyma. A perforation with ragged edges, measuring 4 cm in diameter, was present in the dome of the right diaphragm, and this communicated with the pleural cavity above and with a large subdiaphragmatic abscess below. The liver parenchyma was not involved. However, there was indentation of the diaphragmatic surface of the organ by the large abscess between the liver and the diaphragm. Exploration of the gastro-intestinal tract showed a normal esophagus. The stomach was distended with chyme, and arising from the posterior wall of the midfundal area was a large, gray-pink, lobulated, moderately firm tumor mass which measured 10 by 7 cm. Approximately one fourth of the tumor extended into the lumen of the stomach, while the greater portion extended posteriorly into the lesser peritoneal cavity. The lesion appeared to be originating in the muscle coats of the gastric wall (fig. 3). On the mucosal surface,

Figure 3. Cross section of gastric lesion, showing the nonencapsulated, lobulated structure. The dark, mottled, or mosaic pattern of the cut surfaces is due to hemorrhage and necrosis.

*Lt. Robert K. Bench (MC) USN, Surgical Service.

the lesion produced a "volcanic" type mass with a central crateriform ulceration which measured 2 cm in diameter and approximately 3 cm in depth. The edges or borders of the ulcer were ragged; the ulcer extended deeply into the mass, and was partially filled with necrotic and bloody material. An area of hemorrhage measuring 4 cm in diameter was present in the central portion of the tumor mass. There was no evidence of perforation of the ulcer into the lesser peritoneal cavity; however, fibrinous and fibrous adhesions extended between the serosa covering the lesion and the wall of the lesser peritoneal sac.

The gastrojejunostomy was patent and apparently had been functioning properly. No marginal ulcers were found, and careful examination of the duodenum showed no evidence of mucosal ulceration. No tumor masses other than the large gastric lesion were found. The liver, except for the depressed parenchyma beneath the subdiaphragmatic abscess, was not unusual. The gall bladder appeared normal. Microscopically, the large gastric neoplasm was composed of uniform, interlaced bundles of smooth muscle cells. Mitoses were very rare, and there was no evidence of hyperchromatism of the cells. Focal areas of necrosis were common in the central portion of the tumor along with extensive areas of hemorrhage. No distinct capsule was evident about the tumor mass. Several histologic stains, including hematoxylin-eosin, Masson's trichrome, and phosphotungstic acid-hematoxylin preparations, were carried out, and the microscopic features were characteristic of a leiomyoma (fig. 4).

Figure 4. Photomicrograph of section of leiomyoma of gastric wall, showing proliferating, spindle-shaped smooth muscle cells that are fairly uniform in size and tend more or less to align in a palisade type configuration. ($\times 180$)

Although no sinus tract could be found between the gastric lesion and the right subdiaphragmatic area, it is assumed that the subdiaphragmatic abscess was secondary to an inflammatory process which had its beginning in the gastric ulcer overlying the leiomyoma. The gastric ulcer apparently resulted from pressure necrosis or ischemia of the gastric mucosa by the unusually large leiomyoma, with subsequent erosion and extension of the inflammatory process into the deeper layers of the tumor. Both fibrinous and fibrous adhesions extended from the serosal surface of the tumor in the lesser peritoneal cavity, and it is probable that the infection reached the right diaphragm via this route.

In conclusion, I might add, that although the leiomyoma is probably the most common of benign gastric lesions, it is definitely uncommon for these tumors to become large enough to produce symptoms.

Anatomic diagnoses:

1. Leiomyoma, gastric (posterior; midfundal), with necrosis, hemorrhage, and ulceration
 2. Abscess, subdiaphragmatic, right, with perforation into right pleural space
 3. Empyema, right (1,000 ml)
 4. Pulmonary atelectasis, right, compression type
-

SKEPTICISM IN THERAPEUTICS

One should not be unreceptive to new ideas, but as Osler suggested, one should hold an active skepticism toward new methods and new agents. Simply because some investigator has made a glowing report of the effectiveness of an agent does not always lead to the fact that others can obtain the same effect. This is no reflection on the writer or his scientific honesty or ability. Rather, it is the recognition that enthusiasm at times may color judgment. It has been said that the effectiveness of the therapeutic agent is often proportionate to the personality of him who gives it.

Cushing's Syndrome Treated By Bilateral Total Adrenalectomy

JACOB F. SCHIRMER, *Major, MC, USA*
TIMOTHY N. CARIS, *Captain, USAF (MC)*
WARNER F. BOWERS, *Colonel, MC, USA*
ROBERT E. BLOUNT, *Colonel, MC, USA*

CUSHING'S syndrome, a rare malady occurring predominantly in young women, is a metabolic disorder manifested by moon facies, buffalo type adiposity, hyperglycemia, and impaired glucose tolerance, hirsutism, amenorrhea, muscular weakness, osteoporosis, acne, purplish striae, and, frequently, hypertension. Cushing¹ originally attributed this clinical picture to overactivity of the basophilic cells of the pituitary gland and believed that the causative lesion might be basophilic adenoma of the pituitary gland. He recognized, however, that primary adrenocortical hyperfunction could produce the same clinical picture.

Basophilic adenomata are not always accompanied by the characteristic signs and symptoms of Cushing's syndrome, and in the majority of cases of this malady, no evidence of basophilic adenomata have been found. All the manifestations of this syndrome can be explained on the basis of excessive adrenocortical activity. Basophilic adenoma of the anterior pituitary, hypothalamic lesions, functional neoplasms of the adrenal cortex, and hyperplasia of the adrenal cortex have been found, in different patients, to produce the clinical picture of this entity. Hyperplasia of the adrenal gland is the most commonly incriminated lesion.

The pathologic physiology of Cushing's syndrome and the management of a patient treated at this hospital by bilateral, total adrenalectomy are discussed in this article.

PATHOLOGIC PHYSIOLOGY

The exact basic mechanism involved in this syndrome is not known. The manifestations of the syndrome, however, are known to be associated with overproduction of the adrenocortical hormones and result from abnormalities of the hypothalamic-anterior pituitary-adrenocortical system. It seems reasonable to assume that the mechanism of production of Cushing's syndrome is not always the same. Lesions of the hypothalamus may produce excessive stimulation of

From Brooke Army Hospital, Fort Sam Houston, Tex.

the anterior pituitary gland, resulting in overproduction of adrenocorticotrophic hormone, bringing about adrenocortical hyperactivity. Functional basophilic adenomata of the anterior pituitary gland with overproduction of adrenocorticotrophic hormone likewise would cause adrenocortical hyperactivity and the same clinical picture. Functional neoplasms and primary hyperplasia of the adrenal cortex also result in hyperadrenocorticism. The high incidence of hyperplasia of the adrenal cortex in patients without pituitary basophilism indicates that Cushing's syndrome results from overproduction of adrenocorticotrophic hormone and direct overstimulation of the adrenal cortex. Increased susceptibility of the adrenal cortex to stimulation by the adrenocorticotrophic hormone must also be considered. In any event, whatever factors may exist in Cushing's syndrome, the final picture is of adrenocortical hyperfunction.

In a simplified concept of adrenal cortical function, three groups of hormones may be considered: (1) the glycogenic, (2) the electrolyte-controlling, and (3) the androgenic and estrogenic steroids. In Cushing's syndrome the glycogenic steroids, predominantly, are produced in excess. These steroids (11-oxysteroids) bring about increased gluconeogenesis, protein antianabolism, glycogen storage, and inhibition of the action of insulin. The antianabolic effect on tissue protein results in the appearance of osteoporosis, thinning of the skin, striae, and muscular weakness. The increased gluconeogenesis, excessive glycogen storage in the liver (leading to glycogenolysis), and inhibition of the action of insulin result in impaired glucose tolerance and hyperglycemia. This form of diabetes, of course, is resistant to insulin therapy.

The electrolyte-controlling steroids (desoxycorticosterones) are not controlled by corticotrophic stimulation, but rather by levels of serum electrolytes. They cause increased sodium resorption by the renal tubules and thereby retention of water, and the increased excretion of potassium. This may be the mechanism of the hypertension that is observed in some patients with Cushing's syndrome. Because the production of this hormone is not dependent on stimulation by adrenocorticotrophic hormone, its formation in excess in some cases of Cushing's syndrome (other than in cases of functional adrenocortical neoplasm or primary adrenal hyperplasia) is not entirely understood. The glycogenic hormones, however, also have some influence over sodium retention and potassium loss, and are probably responsible for the development of hypertension in these patients.

The production of the androgenic and estrogenic steroids (17-ketosteroids) is dependent on stimulation by adrenocorticotrophic hormone. When produced in excess, these hormones produce hirsutism and amenorrhea in the female and impotence in the male.

The explanation of the development of buffalo type adiposity and moon facies is unknown. The adrenal cortex may produce another, as

yet unidentified, substance that affects fat metabolism or storage. These phenomena may also be secondary to a disturbance of fat metabolism secondary to the known disturbances of carbohydrate and protein metabolism.

CASE REPORT

A 29-year-old man was admitted to this hospital on 15 March 1954 complaining of frontal headaches and recurring ankle edema of about two years' duration. During a routine physical examination in 1952, he had been found to be hypertensive and was hospitalized. Blood pressure during that hospitalization varied from 120/80 to 170/120 with an average of 160/110 mm Hg. Glucose tolerance tests, liver function tests, excretory urogram, and electrocardiogram at that time were within normal limits. The following year the patient was again hospitalized. Blood pressure was recorded as high as 180/140 mm Hg. Occasional traces of albuminuria were noted, and 24-hour 17-ketosteroid excretion varied from 27.2 to 48.4 mg per 100 ml. Excretory urograms were again found to be within normal limits.

On admission to this hospital, blood pressure was 170/126 mm Hg. The face was moon-shaped, and slight exophthalmos was present along with moderately severe acneform skin rash over the face, back, and chest. There were many ecchymotic areas on both lower extremities, and prominent purple striae were noted over both hips. The patient's weight was 178 pounds and had been maintained at this level by rather rigorous dieting, his previous weight having been 207 pounds.

A white blood cell count was 24,300 μ l with 80 per cent polymorphonucleocytes. Four-hour Thorne test revealed a drop in total eosinophil count from 150 to 0 after administration of adrenocorticotrophic hormone. Urinary 17-ketosteroids were 42.6; 11-oxycorticoids, 4.46; and 17-hydroxycorticoids, 17.6 mg per 100 ml per 24 hours. After a three-day course of 20 units of corticotropin (ACTH) intravenously daily, the urinary 17-ketosteroids rose to 68 mg per 100 ml per 24 hours; 11-oxycorticoids were 5.5; and 17-hydroxycorticoids were 3 mg per 100 ml per 24 hours (fig. 1). Fasting blood sugar

Figure 1. Twenty-four-hour urinary 17-ketosteroid excretion.

February 1956)

as 130 mg and two-hour postprandial blood sugar was 200 mg per 100 ml. Roentgenograms of the skull and cervical, thoracic, and lumbar spine were reported normal. An excretory urogram with retroperitoneal air insufflation revealed some displacement downward of the left kidney by a mass in the adrenal area.

A diagnosis of Cushing's syndrome due probably to adrenal cortical hyperplasia was made, and on 4 June a total left adrenalectomy was performed. The gland was about one and one-half times normal size and histologic examination revealed adrenal cortical hyperplasia. The immediate postoperative course was very gratifying in that the patient's acne began to clear, the purplish striae began to disappear, and he began to lose weight. Urinary 17-ketosteroids dropped to 22.5 mg per 100 ml per 24 hours and the blood pressure gradually approached normal. After about two weeks, however, improvement ceased and the patient noted return of the acne, rise of blood pressure, and recoloration of the striae. On 7 July 1954, the right adrenal gland was totally removed, and this gland was found to be hyperplastic. Since that time his course has been entirely satisfactory. His weight is stable at between 160-164 pounds; the preoperative leg and ankle edema, striae, and acne have entirely subsided; and the blood pressure averages about 150/95 mm Hg (fig. 2). The dusky red color of his face cleared and the moon-face appearance disappeared entirely. Maintenance therapy consists of 25 mg of cortisone daily.

Figure 2. Blood pressure response following total adrenalectomy.

DISCUSSION

Except for osteoporosis, this patient exhibited all the manifestations of Cushing's syndrome. Retroperitoneal air studies revealed only an enlarged left adrenal gland, even though the right and left adrenals were the same size. In an attempt to distinguish between neoplasm and hyperplasia, an ACTH test was performed (table 1).

It was thought that if adrenal neoplasm were present, the administration of ACTH would not significantly alter the total 24-hour urinary excretion of 17-ketosteroids and 11-oxysteroids because such a neoplasm functions independently of anterior pituitary control; whereas if hyperplasia were present, administration of ACTH would stimulate even more steroid production by the adrenal cortex. In this patient, ACTH administration produced an increase of 17-ketosteroids and 11-oxysteroids, suggesting the presence of adrenal hyperplasia. Jailer, Gold, and Wallace¹ recently evaluated a cortisone test for differentiation between adrenal hyperplasia and adrenal cortex neoplasia. Essentially the same principle is involved. The administration of cortisone inhibits adrenocorticotrophic hormone production. In adrenal cortical neoplasia, decrease in corticotropin produces no change in 17-ketosteroid urinary excretion, while in hyperplasia of the adrenal cortex, a decrease in 17-ketosteroid excretion occurs.

TABLE 1. ACTH test

Urinary steroids	Excretion in 24 hours	
	Base line levels	Levels after 3 days of 20 units ACTH intravenously
17-ketosteroids	42.6 mg	68 mg
11-oxycorticoids	4.46 mg	5.5 mg
17-hydroxycorticoids	17.6 mg	3 mg

The surgical approach to the adrenal gland may be transthoracic, transperitoneal, or extraperitoneal. We favor the extraperitoneal approach in most instances and it was used in this patient. Exploration of one adrenal gland allows rather accurate estimation of the condition of the other gland. If the exposed gland is small and hypoplastic, this is presumptive evidence that the contralateral gland contains primary cortical tumor. The finding of tumor in the first exposed gland, however, does not necessarily mean that tumor is not also present in the other gland. If the exposed gland is large and hyperplastic, the other gland is very probably also large and hyperplastic. Some authors advocate the removal of certain portions of hyperplastic glands or of all of the first explored gland and a portion of the remaining gland. The patient in these cases almost always either requires some form of maintenance therapy or is subject to recurrence of his disease. Sprague, Kvale, and Priestly² found that in virtually all cases the patients who did not receive maintenance therapy had recurrence of preoperative symptoms and signs. Experiences with totally adrenalectomized patients being treated for metastatic carcinoma of the breast will be reported by one of us (WFB) subsequently.³ In view of the ease with which patients ordinarily can be man-

aged following bilateral total adrenalectomy, we believe that subtotal adrenalectomy, with the attendant risk of recurrence of disease, is inferior to total adrenalectomy for adrenal cortical hyperplasia.

Successful bilateral total adrenalectomies for Cushing's syndrome also have been reported by Sprague and associates and Abbott et al.⁶

SUMMARY

A discussion of Cushing's syndrome, its manifestations and pathologic physiology has been presented. Successful treatment of a male patient with this condition by bilateral, total adrenalectomy is reported. We believe that because the productivity of residual tissue left after operation cannot be at all accurately ascertained at the time of operation, in order to cure the disease one must remove the entire adrenal gland. We believe that adrenalectomized patients ordinarily are not difficult to manage and that total adrenalectomy with postoperative cortisone administration is no more dangerous to the patient than is almost total adrenalectomy with cortisone management.

In every illness there are periods when what the patient needs most is to be left in peace—not to be stirred up, even by sympathetic interest. And there are other periods when any help is desirable even if it means facing fairly severe strain or accepting pain. The general practitioner has to decide what the patient's requirements really are. He has to decide at his own peril and at that of his patient. For his solution of the problem of "when to start" has important consequences for the further development of the illness.

Congenital Toxoplasmosis

HOWARD A. PEARSON, Lieutenant (junior grade) (MC) USN

TOXOPLASMOSIS in human beings is a comparatively recently described entity. The genus *Toxoplasma* was established in 1909 by Nicolle and Manceaux¹ to include a microorganism which they discovered in the gondi, a North African rodent (*Ctenodactylus gondi*). Appropriately, they called their find, *Toxoplasma gondii*. The genus has only this one species including a number of parasites of warm-blooded animals throughout the world. The precise nature of the parasite is still controversial; however, by general agreement, it is included among the protozoa. *Toxoplasma* is an obligate parasite which lives in the tissue fluids and cells of the host. Only the erythrocyte is apparently not infected. Multiplication is by binary fission. The means of transmission of the parasite is uncertain. It is believed that rodents and birds constitute the reservoir; but as yet no vector has been identified.

The first confirmable report of human toxoplasmosis was written by Jankū² in 1923 who described the ocular changes of chorioretinitis, and who demonstrated the parasite in the eye. In 1942 Paige, Cowen, and Wolf³ proved prenatal infection by demonstrating the findings of disseminated toxoplasmosis in a hydrocephalic infant who was delivered after craniotomy. Recently, typical parasites have been demonstrated in the placenta of an infected infant.⁴ The disease usually produces no symptoms in the mother. It has been shown consistently that mothers who produce affected children have high titers of complement-fixing and dye antibodies. The disease is more serious in younger patients; indeed the effect on the fetus is devastating. Congenital toxoplasmosis, though a rare disease, should be included in the differential diagnosis of certain frequently encountered signs and symptoms in pediatric practice. These are mental retardation, convulsions, blindness, hydrocephaly, or microcephaly.

CASE REPORT

A nine-month-old infant was referred to this hospital for evaluation of blindness and retardation. She was the second child of a white mother and a Filipino father. The mother had a normal four-year-old son, and had had a three-month spontaneous abortion prior to the birth of the patient. The mother had always lived in the Washington area; how-

From U. S. Naval Hospital, Bethesda, Md.

ever, the father made several trips to the Caribbean area prior to and during the patient's gestation. Pregnancy was uneventful except for a few weeks during the second trimester. At this time, the mother had rather severe muscle aches and cramps and general malaise. She did not consult a physician about this, and the symptoms regressed spontaneously.

The child was born at term; birth weight was 4 pounds 13 1/2 ounces. The child was a moderate feeding problem, and several changes of formula were made. However, after a few weeks her general appearance, feeding, and weight gain were satisfactory. She was thought to be a normal child except that she was slightly "jumpy" and her stools were slightly increased in number. Blood counts and urinalyses in the nursery were normal.

Despite normal feeding and weight gain, it soon became apparent that the child was not developing normally. Virtually no progress was made in the motor sphere. At nine months she could not support her head steadily, sit, or turn over. Her eyes had never focused, and her parents had discovered her to be blind.

Physical examination revealed a chubby, placid female infant. Her weight was 21 3/4 pounds (75th percentile); she was 27 inches in length (30th percentile); her head circumference was 16 1/2 inches (less than 3d percentile). The anterior fontanelle was open and of normal size and turgor, and the sutures were not separated.

The eyes showed bilateral wandering motions, but not true nystagmus. The eyes did not move synchronously. There was a bilateral red reflex. The pupils were round but did not respond to light. The child did not blink when light or moving objects were directed at her eyes. She was thought to be totally blind. Funduscopically the vessels were normal and most of the retina was of normal color and pigmentation. The optic disks were dead white in color, showing typical optic atrophy. In the macular region bilaterally were punched-out areas, white in color, about one third the size of the disks. These lesions showed punctate pigment deposits.

Hearing was grossly intact. No teeth had erupted. The heart and lungs were normal. The liver edge was palpable three centimeters below the costal margin in the midclavicular line. No other organs or masses were palpated.

The child moved all extremities, and would withdraw these when stimulated. The deep tendon and abdominal reflexes were normal. There were bilateral extensor plantar reflexes. There was moderate rigidity of the lower extremity flexors. When the child was disturbed, she had clonic movements of the left arm and leg.

Complete blood cell count, serologic test for syphilis, and Vollmer tuberculin patch test were normal. Lumbar puncture demonstrated clear fluid under no increased pressure. This fluid contained 7 red blood

cells, 4 neutrophils, and 1 lymphocyte per μ l. The sugar was 61; chlorides, 738; and protein, 60 mg per 100 ml.

Electrocardiographic findings were within normal limits for the age of the patient. The electroencephalogram showed generalized abnormality, with maximum slow activity over the left frontal and temporal regions. Roentgenograms of the skull showed extensive intracranial calcifications (figs. 1 and 2).

Roentgenograms of the extremities showed normal ossification centers for the child's age. No soft tissue calcification was noted.

Ventricular aspiration demonstrated clear fluid with 1 red blood cell, 2 neutrophils, and 1 lymphocyte per μ l. The protein was 37. 2 and the sugar was 44 mg per 100 ml. No organisms were demonstrated in the ventricular fluid.

Ventriculograms showed massive, symmetrical dilatation of the lateral and third ventricle with a block, probably in the region of the aqueduct of Sylvius (figs. 3 and 4).

The hospital course was uneventful, and the patient tolerated the various procedures well. It was believed that the patient's disease was inactive and that no medical therapy or chemotherapy was indicated. A neurosurgical consultant advised no surgical intervention for the hydrocephalus. Since discharge the patient's condition has not changed, and arrangements are being made for institutionalization.

DISCUSSION

The classical features of the syndrome of congenital toxoplasmosis, namely, chorioretinitis, internal hydrocephalus, and intracranial calcifications, have been reported in many cases. The eyes and central nervous system appear extremely susceptible to the effects of the parasite. However, a parasitemia occurs during the disease, and in autopsy specimens the parasite has been demonstrated in the heart, muscles, and other viscera as well as the brain and eye.⁴

PATHOGENESIS OF OCULAR LESIONS

The parasite is blood-borne to the eye, where granulomatous reaction and necrosis occurs. The early lesion is a localized area of retinal edema with a central umbilicated ulceration. As the edema regresses, the destruction of the choroid and retina becomes apparent and the underlying sclera shows through the destroyed layers of the choroid and the retina. Irregular pigmentation, heavier at the periphery, is then seen. The lesions tend to be bilateral and symmetrical; the macular areas are very frequently involved. The media is clear. Optic atrophy of the secondary type is often seen as a result of the increased intracranial pressure of the internal hydrocephalus. Depending on the degree

Figure 1. Lateral view of the skull showing extensive calcifications, the shape of which suggests that of dilated lateral ventricles. Figure 2. Posteroanterior view of the skull showing linear distribution of the calcifications. Symmetrical calcifications in the area of the basal ganglia and a large, thrombosed vessel are also noted.

Figure 3. Ventriculogram demonstrating massive internal hydrocephalus with dilatation of the lateral and third ventricles. Figure 4. Posteroanterior projection showing typical periventricular distribution of calcifications.

of retinal involvement, for the lesions of chorioretinitis can be extensive, and depending upon whether optic atrophy is present, the child may have some useful vision or be totally blind. Because of the frequent macular involvement, central vision is poor.

PATHOGENESIS OF THE INTERNAL HYDROCEPHALUS

During the parasitemia, the organism enters and destroys many of the ependymal cells lining the ventricles. In the relatively large lateral and third ventricles, this causes only loss of continuity of the ependymal layer. However, in the narrow confines of the aqueduct of Sylvius, the inflammation, edema, and tissue necrosis often cause obstruction of the cerebrospinal fluid flow. Closure of the foramina of the fourth ventricle also is seen. This obstruction causes the internal hydrocephalus.

PATHOGENESIS OF INTRACRANIAL CALCIFICATIONS

The intracranial calcifications of congenital toxoplasmosis are characteristically periventricular and diffuse. The cause of this distribution is speculative; however, Frenkel and Friedlander⁶ suggested an interesting theory: The ventricular fluid in these patients has repeatedly been shown to be a potent source of toxoplasma antigen and often contains organisms. The ependyma, where intact, is impermeable to the cerebrospinal fluid. However, where ependymal destruction has occurred, fluid may seep into the surrounding brain tissue, facilitated by the increased intracranial pressure. As the antigen-rich fluid permeates the tissue, it encounters extracellular fluid. Because the antibody mechanism of the host has been stimulated, the blood and extracellular fluid contain free toxoplasma antibody. When the antigen-antibody combination takes place in the periventricular tissue, further inflammation and tissue necrosis occur. After the inflammation subsides, repair and calcification occur. Perivascular hemorrhage, vascular thrombosis, and infarction may also develop in the area.

SUMMARY

A case illustrating the classical findings of congenital toxoplasmosis is presented. Chorioretinitis, internal hydrocephalus, and intracranial calcifications which are characteristic of this syndrome were present. It is suggested that congenital toxoplasmosis be included in the differential diagnosis when mental retardation, convulsions, blindness, hydrocephaly, or microcephaly are encountered. Fundusoscopic examination for chorioretinitis and roentgenographic examination of the skull for intracranial calcifications offer the most satisfactory means of establishing the diagnosis.

WHAT IS A G. P.?

"The first step . . . is to decide who is a general practitioner. This is not as easy as it appears. So wide is the field of general practice that to say a man is a general practitioner is not much more informative than to say that he is a surgeon. After much deliberation the [Canadian] College of General Practice arrived at the negative definition that 'he is a doctor who does not limit his practice to any one field of medicine.' A popular identification—flippant but descriptive—is: 'A general practitioner is an internist who does as much surgery as the hospital facilities, and his colleagues, will permit.'"

Cortisone in Treatment of Acute Pancreatitis Associated With Mumps Epidemic Parotitis

AUGUSTUS F. BLOODWORTH, *Captain, USAF (MC)*
STANLEY L. COHEN, *First Lieutenant, USAF (MC)*

PANCREATITIS associated with mumps (epidemic parotitis) is a recognized medical entity occurring frequently enough that early recognition and treatment is important in a serious and possibly fatal disease complication. The diagnosis is suggested by the appearance of epigastric pain, nausea, and vomiting, with associated tenderness on deep palpation. The most striking diagnostic laboratory finding is an elevation of the serum amylase.

The use of adrenal corticosteroids has been favorably reported in treatment of acute hemorrhagic pancreatitis.^{1,2} The following is a report of a case of acute pancreatitis, associated with mumps, in which the use of cortisone was felt to be lifesaving.

CASE REPORT

A 17-year-old airman was admitted to the medical service of this hospital on 18 April 1955, with a chief complaint of pain in the right parotid area with associated discomfort on swallowing for 1 day prior to admission.

The patient had had "mumps" on the left side at the age of 6. Physical examination on admission revealed a moderately ill white man who had definite swelling and tenderness over his right parotid gland and associated inflammatory changes around the orifice of Wharton's duct on the right. His temperature was 99.8° F. There were no other positive physical findings.

A diagnosis of mumps was made, and the patient was placed on strict bed rest, 5 mg. of diethylstilbestrol daily, sedation, and analgesics. Temperature elevations to 99.8° F. occurred daily during the first 3 hospital days. On the fourth day the patient developed a bilateral epididymitis, manifested by pain and tenderness over both epididymal areas, with associated temperature of 101.6° F. This was managed with ice bags to the involved area, and opiates for pain. Although the symp-

¹From U. S. Air Force Hospital, Lake Charles Air Force Base, La.

toms improved on the fifth day, the patient's temperature was elevated to 103° F., and that evening this was accompanied by a vague pain in the upper abdomen. On the sixth day, abdominal pain was more severe and radiated through to the back. Examination revealed definite tenderness over the entire upper abdomen. The patient's temperature was 104° F. Nausea, vomiting, and flatulence ensued. Serum amylase was 80 Somogyi units (normal 20-40). A diagnosis of pancreatitis was evident. Treatment, consisting of gastric suction, intravenous feedings, and small doses of regular insulin, anticholinergics, and opiates, was instituted. Penicillin and streptomycin were administered parenterally. The patient seemed to be improving symptomatically, although his temperature remained elevated.

Late during the sixth hospital day the patient became very weak and appeared to be in shock. His rectal temperature was 105.6° F. and tachycardia (pulse 130) was present. Following this, the patient became stuporous and was placed on the dangerously ill list. His blood cell count revealed a leukocytosis with a shift toward immature forms. Blood cultures, liver function studies, serum electrolytes and blood glucose revealed no significant abnormalities.

Cool water enemas and spongings with alcohol were given without any significant temperature change. One hundred milligrams of cortisone was given intramuscularly, and followed with 50 mg. every 6 hours. By the morning of the seventh hospital day there was dramatic improvement. The patient was rational, feeling stronger, and his temperature was declining.

Later in the day the patient developed diffuse bronchospasm which responded to sedation, bronchodilators, and alevaire (brand of a detergent superinone) inhalations. His temperature became normal on the eighth hospital day. Cortisone was continued at a dosage of 50 mg. intramuscularly, every 8 hours, for 3 more days. Repeat serum amylase determination was 30 Somogyi units. By the twelfth hospital day the patient was ambulatory and feeling well, except for slight epididymal pain. On the eighteenth hospital day the patient was discharged on convalescent leave.

DISCUSSION

The serum amylase of most patients with epidemic parotitis is elevated during the first few days of illness. This is believed to be associated with the acute inflammatory process in the parotid glands rather than with an accompanying pancreatitis.⁹ However, a serum amylase of twice normal value is pathognomonic of acute pancreatitis in the presence of signs and symptoms such as those seen in our patient. Although an anticholinergic drug, banthine (brand of methantheline bromide), and gastric suction afforded temporary relief, cortisone reverted a downhill course to one of recovery.

THE DOCTOR'S SKIN

The problem of industrial dermatoses is a major one, but no working man is exposed to more irritating or potentially sensitizing substances than the physician. It is not surprising that each year surgeons or obstetricians must find other fields of medicine into which to enter because their hands cannot tolerate the necessary scrubbing. Some promising trainees for private medical practice must direct their future planning toward administrative positions for the same reason. Much of this could be avoided if proper care is taken of the skin. . . . The doctor is prone to treat himself with all sorts of self-medication, which may be injudicious and sometimes actually harmful. Treat your skin kindly as you are going to need it for a long time.

in Journal of the Tennessee State

Medical Association, pp. 400 and 403, Oct. 1954

MEDICAL WISDOM

All the power of tongue and pen, and all the wisdom of textbook and lecture, can never teach a doctor the knowledge of when to probe and when to leave alone, when to chide and when to reassure, when to speak and when to keep silent. They are private mysteries with a different solution for every one of the million permutations of personality involved between a doctor and his patient.

—RICHARD ASHER, M. D.

in Lancet

p. 738, Apr. 9, 1955

A MESSAGE FROM THE A. M. A.

The January issue of the *U. S. Armed Forces Medical Journal* carried the first in a series of articles to acquaint physicians in uniform with the organization, function, history, and purpose of the American Medical Association. Last month a brief history and the purpose of the Association were covered, as well as the membership requirements and types of membership.

The policy-making body of the Association is the House of Delegates which meets in June and December of each year. The Board of Trustees directs all activities of the Association between these meetings. The Secretary-General Manager supervises all activities of the councils, bureaus, and committees between meetings of the Board.

Thirteen standing committees serve the House of Delegates and Board of Trustees. Four councils report directly to the House of Delegates, and seven councils and two committees report to the Board of Trustees. Councils and committees are composed of from 5 to 18 physicians. Members are either elected by the House of Delegates or appointed by the Board of Trustees. Councils and committees decide policies on all activities under their jurisdiction, subject to approval by the Board of Trustees and the House of Delegates. Most councils and committees have a full-time staff at A. M. A. headquarters which implements their programs. Each staff is headed by a secretary. Those committees without a full-time staff are serviced by the office of the Secretary-General Manager.

One of the standing committees of the Board of Trustees is the Council on National Defense. This Council is a direct outgrowth of a special committee appointed by the House of Delegates in December 1945 to study the experiences of medical officers during World War II with special reference to opportunities for study, research, actual treatment of the sick, rotation of medical assignments, and use of medical officers for nonmedical duties.

The responsibilities of the Council on National Defense generally fall into two areas—military medical affairs and civil defense matters as they relate to medical preparedness. Because of the increased scope of activities in these two areas within the

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.
—Editor.

past few years, two committees of the Council were established—the Committee on Military Medical Affairs and the Committee on Civil Defense.

The Council assists the Armed Forces, as well as state and federal civil defense authorities, with medical and health problems and acts as a liaison with allied health agencies regarding personnel, facilities, and material needed in time of national emergency. It assists in planning for the distribution of medical and allied personnel in an all-out emergency, aids with national and state disaster relief plans, and co-ordinates the work of the state emergency medical service committees.

In the field of military medical affairs, the Council and its Committee work closely with the Surgeons General of the armed services and the Assistant Secretary of Defense (Health and Medical) in formulating plans and procedures designed to improve medical care for members of the Armed Forces. In this way, they also assist in ensuring the most advantageous use of the country's medical manpower. For several years the Council has conducted a continuing survey among physicians being released from active military service. The survey is designed to obtain information on the utilization of physicians and medical staffing conditions in the Armed Forces and to solicit comments and suggestions concerning the improvement of the military medical corps. Reports, covering a six month's summary, are published in the *Journal of the American Medical Association*, and copies are furnished to military representatives. These reports have served as a guide for discussions with the military departments.

Another activity of the Council and its Committee on Military Medical Affairs is a placement service to furnish assistance to physicians being released from active military service by providing information pertaining to available civilian medical opportunities. This program has been well received and the Council has furnished placement assistance to over 2,000 physicians. The Council also assists State Volunteer Medical Advisory Committees to the Selective Service System in replacing deferred physicians who have a military obligation. The Council also closely follows federal legislative proposals which, if enacted, would affect military medical activities.

The Council attempts to ensure a proper balance between the medical needs of the civilian population and the Armed Forces, by working closely with the National Health Resources Advisory Committee, the National Advisory Committee to the Selective Service System, and state advisory committees to Selective Service.

The Council firmly believes that the development of a strong and attractive medical service of the Armed Forces and federal agencies is in the best interest of the public welfare, and that the development of such services depends on the confidence and intimate collaboration of the medical profession of this nation.

Next month, civil defense activities of the Council on National Defense and other operations of the American Medical Association will be discussed.

DEATHS

CUNOV, *Harvey Frank*, Major, MSC, USAR, San Antonio, Tex.; 3d Army Area Medical Laboratory, Fort McPherson, Ga.; graduated in 1929 from the Michigan State College, East Lansing, Mich.; commissioned a First Lieutenant 17 February 1943; ordered to active duty 4 March 1943; died 23 November 1955, age 51, of myocardial infarction.

DE FOREST, *Julia Ann*, Lieutenant (jg) (NC) USNR, Douglas, Wyo.; U. S. Naval Station, Kodiak, Alaska; graduated in 1951 from the St. Mary's School of Nursing, Rochester, Minn.; appointed an Ensign 17 March 1953; ordered to active duty 1 May 1953; died 2 December 1955, age 25, in Kodiak, Alaska.

FRANK, *Elliot Herman*, Major, DC, USAR, Wantagh, Long Island, N. Y.; 2104th Service Unit, Camp A. P. Hill, Va.; graduated in 1941 from the University of Indiana School of Dentistry, Indianapolis, Ind.; commissioned a Major 28 February 1955; ordered to active duty 9 May 1955; died 5 September 1955, age 42, in Fredericksburg, Va., of coronary thrombosis.

FRAZEE, *Edward Blackwell*, Lieutenant Colonel, MSC, USA, Sioux Falls, S. D.; Landstuhl Army Medical Center, Germany; graduated in 1935 from the Lehigh University College of Chemistry, Bethlehem, Pa.; commissioned a Second Lieutenant 27 September 1941; died 23 October 1955, age 43, in Germany, of injuries received in an automobile accident.

GRANT, *Seymour*, Captain, MC, USAR, Sepulveda, Calif.; Ryukyus Army Hospital, Okinawa; graduated in 1950 from the University of Michigan Medical School, Ann Arbor, Mich.; commissioned a First Lieutenant and ordered to active duty 25 August 1953; died 24 November 1955, age 31, in Okinawa.

ORMAND, *Margaret Louise*, Major, ANC, USA, Richmond, Va.; William Beaumont Army Hospital, Fort Bliss, Tex.; graduated in 1934 from the Petersburg Hospital School of Nursing, Petersburg, Va.; commissioned a Second Lieutenant 2 February 1941; died 13 November 1955, age 42, at the Deming Ladies Hospital, Deming, N. Mex., of injuries received in an automobile accident.

Palmer, E. D., Lt. Col., MC, USA: Dysphagia lusoria; clinical aspects in adult. *Ann. Int. Med.* 42: 1173-1180, June 1955.

Promotions of Officers

The following officers of the military medical services on active duty in the Army, Navy, and Air Force have recently received temporary promotions to the rank indicated:

MEDICAL CORPS

ABELL, Thomas G., Lt., USN
 AMSDEN, Neal F., Lt., USN
 ANDERSON, Lewis D., Lt., USN
 ARBONAFIGUEROA, Joseph A., Lt., USN
 ASHCROTH, Charles F., Lt., USN
 BAKER, Larry D., Lt., USN
 BARRICK, Richard H., Lt., USN
 BAUER, Clifford T., Lt., USN
 BECKER, Bruce A., Lt., USN
 BELL, George R., Lt., USN
 BENNETT, Wayne E., Lt., USN
 BEPMAN, Irwin, Lt., USN
 BLOCHER, Emanuel M., Lt., USN
 BLUM, Harold P., Lt., USN
 BONNEY, James H., Lt., USN
 BOWLEN, Paul P., Lt., USN
 BRANDT, Henry E., Lt., USN
 BRIDGE, Robert E., Lt., USN
 BRINK, Paul E., Lt., USN
 BRODIE, Sheldon J., Lt., USN
 BROWN, Dudley E., Jr., Lt., USN
 BROWN, Jacob V., Lt., USN
 BROWN, Philip W., Jr., Lt., USN
 BURKE, Albert V., Lt., USN
 BURKE, Robert A., Lt., USN
 BURRIS, Boyd L., Lt., USN
 BUTLER, Milton C., Jr., Lt., USN
 CANNON, Joseph H., Jr., Lt., USN

Reviews of Recent Books

HEART DISEASE, Its Diagnosis and Treatment, by *Emanuel Goldberger, M. D., F. A. C. P.* 2d edition. 781 pages; 298 illustrations on 107 figures; 5 tables. Lea & Febiger, Philadelphia, Pa., 1955. Price \$12.50.

It is the intent of the author to present a complete, concise, and thoroughly up-to-date textbook of clinical cardiology. In this aim he succeeds admirably. By enlarging the first edition about 25 percent, numerous recent topics of clinical interest are included which are not elsewhere available in comparable textbook form.

Established concepts are simply presented with emphasis on clinical practicability as opposed to historical development. Similarly, recent trends are presented in condensed form which, albeit opinionated, are generally conservative while being fair. Included are sections on balistocardiography, diagnostic technics applicable in the evaluation of lesions amenable to heart surgery, newer drugs, et cetera.

Other features of merit are: A bibliography mainly applying to work done in the last 5 to 10 years; unusually complete and accurate index and table of contents; mainly diagrammatic (as opposed to photographic) illustrations; clear and direct style; and excellent format. The biggest drawback is the number of one-sided opinions authoritatively presented.

This volume will be most appreciated by physicians in diverse fields, who are interested in a thoroughly modern text of cardiology of unusually wide coverage, yet relatively brief in form.

—R. B. DICKERSON, *Lt. Col., MC, USA*

PRACTICAL NEUROLOGY, by *Leo M. Davidoff, M. D. and Emanuel H. Feiring, M. D.* 442 pages. Landsberger Medical Books, Inc. Distributed solely by the Blakiston Division of the McGraw-Hill Book Co., Inc., New York, N. Y., 1955. Price \$7.

This is the latest in a series of handbooks for the general practitioner. It includes a wide survey of neurologic methods, diagnosis, therapy, and results, presented in a clear, concise manner. The amazing completeness as to essentials, in so small a text, is a tribute to the authors. Should some wonder at the ability of one of America's leading neurosurgical teams to produce a basic general neurologic text of this nature, one has only to note their diagnostic criteria and therapeutic principles to realize their penetrating grasp of the material, which varies from tumors of the nervous system through inflammatory and degenerating processes.

It is recommended, not only to the general physician, but to all interested in a ready reference on fundamental elements of neurologic disease.—*JAMES F. HAMMILL, Lt. Col., MC, USA*

BLOOD SUPPLY AND ANATOMY OF THE UPPER ABDOMINAL ORGANS, With a Descriptive Atlas, by *Nicholas A. Michels*, M. A., D. Sc. (Louvain). 581 pages; 172 illustrations, including 166 in color. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$24.

This anatomy book is written for study and use by surgeons, but is so complete and detailed in its descriptions and illustrations that I am sure it will be consulted by anatomists as well. The anatomy of the upper abdominal organs is a subject in which every surgeon should be well versed, and this volume presents it so well and completely that it should be required reading and study for every surgeon, and particularly for every young resident surgeon.

The anatomic descriptions of the organs and their blood supply are complete in nearly all details. The charts and illustrations show clearly the detailed anatomy of the areas, and present, as shown in no other available text, the innumerable variations in anatomy which the surgeon may encounter in upper abdominal operations.

The surgical literature today is replete with reports of catastrophes precipitated by surgeons operating in the upper abdomen. If the detailed anatomy in this book were common knowledge to all surgeons, many of those accidents and their unfortunate results could surely be avoided.

—FELIX P. BALLENGER, *Comdr. (MC) USN*

THE HEMORRHAGIC DISORDERS, A Clinical and Therapeutic Approach, by *Mario Stefanini*, M. D. and *William Dameshek*, M. D. 368 pages; illustrated. Grune & Stratton, Inc., New York, N. Y., 1955. Price \$11.75.

This is an authoritative, amply illustrated, clearly written volume on the clinical and laboratory diagnosis and treatment of the hemorrhagic disorders. In contrast to most other current texts on this subject, it gives proper emphasis to other hemostatic defects in addition to those of the coagulation mechanism, namely, defects in the vascular, platelet, and fibrinolytic mechanisms.

The authors have made this book thoroughly up to date by giving due consideration to the "newer" entities of "dysproteinemic," vascular, and fibrinolytic purpuras as well as hemorrhagic disturbances of pregnancy and the puerperium. They have even furnished an addendum of significant findings reported in the literature in early 1955.

Of especial practical value to the practicing physician are the many time-saving and space-saving diagnostic tables, including "screening tests" and therapeutic tables, as well as detailed directions on therapy. Stimulating to the investigator in this and related fields will be the several theories suggested for the cause or pathogenesis of various hemorrhagic disorders.

The authors have admirably achieved their objective of writing a practical, well-balanced book on this important subject. At the same time, they have accomplished this in a scholarly manner.

—H. LEONARD JONES, *Comdr. (MC) USN*

TABLE 1. *Vehicular fatalities by type of accident in U. S. Navy and Marine Corps personnel, 1952 through 1954*

TABLE 1. *Vehicular fatalities by type of accident in U. S. Navy and Marine Corps personnel in U. S. Government vehicles only (1952 through 1954)—Continued*

-
- a. In one fatal accident, a passenger was thrown out and escaped with spinal injuries.
 - b. Jeep, rolled over, killing passenger; driver was thrown out and escaped injury.
 - c. In one fatal accident, eight other passengers in back escaped injury.
 - d. In one fatal accident of each type, others in vehicle who were not thrown out were only slightly injured.
 - e. Drowned when vehicle ran off pier or turned over in shallow water.
-

Two vehicular deaths not tabulated occurred on aircraft carriers at sea. In each of these, an aircraft towing truck fell into an elevator well, the driver falling first and the truck on top of him. They are not included in the tabulation, as speed and design of this vehicle would not seem to call for use of seat belts.

these same 33 persons would have been killed had they been kept in the vehicle by seat belts, although in a number of instances they actually were thrown out before being pinned down or rolled on.

On the other hand, in 13 of the 20 deaths in accidents of panel and pickup trucks, carryalls, and other hard-top vehicles, the chances that a seat belt would have prevented the fatality appear to have been very good. In 12 cases the victim was thrown out of the cab or enclosed part of the vehicle; however, in one of these he was probably too drunk to have used a belt, leaving 11 who might have been saved. In four of the accidents the victim was fatally injured while remaining in the cab; however, in one case he was crushed by the steering wheel and in another he probably was too drunk to have used a belt, leaving 2 more who might have been saved. In three deaths the victim was drowned when the vehicle turned over into a rice paddy or plunged off a pier; and the remaining man killed was sitting on the rear of a pickup truck and was thrown out.

In the one ambulance accident involving a fatality, not only was the driver killed but also the passenger (a medical officer) was thrown about and critically injured. Considering that in 1950 another medical officer was killed in a Navy ambulance collision by being thrown from the right front seat, it would seem especially important to provide safety belt protection for the passenger on the front seat of a standard ambulance.

There were 14 deaths caused by falls from vehicles not involved in accidents. Seven of the victims were killed by falling from fire, crash, or gasoline trucks; usually when the truck was making a sharp turn. Two of these were passengers seated in the cab, and five were men standing on the truck, who lost their grip on a turn or while changing position. The two seated passengers certainly would have been saved by seat belts. It also would appear warranted to consider the use of quick-release belts to hold standees in place on certain types of fire and crash vehicles. Four of the 14 victims fell off the rear end or side rail of 6 by 6

TABLE 1. *Vehicular fatalities by type of accident in U. S. Navy and Marine Corps personnel in U. S. Government vehicles only (1952 through 1954)—Continued*

- a. In one fatal accident, a passenger was thrown out and escaped with spinal injuries.
- b. Jeep, rolled over, killing passenger; driver was thrown out and escaped injury.
- c. In one fatal accident, eight other passengers in back escaped injury.
- d. In one fatal accident of each type, others in vehicle who were not thrown out were only slightly injured.
- e. Drowned when vehicle ran off pier or turned over in shallow water.

Two vehicular deaths not tabulated occurred on aircraft carriers at sea. In each of these, an aircraft towing truck fell into an elevator well, the driver falling first and the truck on top of him. They are not included in the tabulation, as speed and design of this vehicle would not seem to call for use of seat belts.

those same 33 persons would have been killed had they been kept in the vehicle by seat belts, although in a number of instances they actually were thrown out before being pinned down or rolled on.

On the other hand, in 13 of the 20 deaths in accidents of panel and pickup trucks, carryalls, and other hard-top vehicles, the chances that a seat belt would have prevented the fatality appear to have been very good. In 12 cases the victim was thrown out of the cab or enclosed part of the vehicle; however, in one of these he was probably too drunk to have used a belt, leaving 11 who might have been saved. In four of the accidents the victim was fatally injured while remaining in the cab; however, in one case he was crushed by the steering wheel and in another he probably was too drunk to have used a belt, leaving 2 more who might have been saved. In three deaths the victim was drowned when the vehicle turned over into a rice paddy or plunged off a pier; and the remaining man killed was sitting on the rear of a pickup truck and was thrown out.

In the one ambulance accident involving a fatality, not only was the driver killed but also the passenger (a medical officer) was thrown about and critically injured. Considering that in 1950 another medical officer was killed in a Navy ambulance collision by being thrown from the right front seat, it would seem especially important to provide safety belt protection for the passenger on the front seat of a standard ambulance.

There were 14 deaths caused by falls from vehicles not involved in accidents. Seven of the victims were killed by falling from fire, crash, or gasoline trucks; usually when the truck was making a sharp turn. Two of these were passengers seated in the cab, and five were men standing on the truck, who lost their grip on a turn or while changing position. The two seated passengers certainly would have been saved by seat belts. It also would appear warranted to consider the use of quick-release belts to hold standees in place on certain types of fire and crash vehicles. Four of the 14 victims fell off the rear end or side rail of 6'

trucks or dump trucks, and three died from falling between the frame and treads of caterpillars.

If seat belts had been installed in hard-top vehicles only, and if men had been successfully indoctrinated in using them (which will take considerable time and effort and never be fully achieved), a saving of 15 lives is the maximum benefit that could have been expected on mortality alone. If all these deaths had been prevented, the monetary saving would have amounted to over \$470,000. This is only the beginning of savings possible, as many grave and costly injuries would at the same time have been prevented or converted to minor ones.

The lack of adequate data in many reports of death is a serious handicap in estimating the value of preventive measures, either potential or realized. Even more sketchy is the data on injuries which are survived. The latter are far more frequent and often much more costly in time, medical manpower, and money, than deaths. Data of immense value for planning and for subsequent evaluation could be obtained if more detailed information were required on all automobile injuries involving more than a few sick days. A minimum of 5 or 10 days might be specified so as to keep the burden of reporting within reason. The causative vehicle, the method in which injury was sustained, the presence or applicability of safety devices, all need a statistical evaluation.

SUMMARY

Deaths of Navy and Marine Corps personnel in government-owned ground vehicles are analyzed for a three-year period. More than half of these (41 out of 72) occurred in open-top military type vehicles, a higher proportion than would be expected during peacetime. Provision of seat belts in open-top vehicles would probably not have reduced but would more likely have increased these fatalities. In only five deaths did this type of vehicle remain upright when involved in an accident, whereas in 33 it rolled over. By comparison, 10 persons who escaped death in rollover accidents by being thrown out would probably have been killed if they had been kept in by seat belts.

In hard-top vehicles involved in accidents, 15 of 20 deaths would probably have been prevented if the victim had been wearing a seat belt, although in two cases he was too drunk to have used one. In 12 of the deaths, the victim was thrown from the cab, with or without rollover. Front seat passengers in ambulances appear to be especially at risk when not provided with seat belts.

Seven deaths, or one out of 10, occurred in falls from fire and crash trucks when the vehicle was merely making a turn. In two of these, the man slid off a seat. In these two cases, seat belts

would certainly have prevented the accidents had they been worn. Quick-release belts for standees should also be considered for this type of vehicle.

If seat belts are used in hard-top vehicles, potential monetary savings on deaths alone amount to \$470,000 in three years. In addition, many serious and costly injuries would be prevented.

Weighing the cost of preventive measures against their savings, both in deaths and in the far more frequent nonfatal but costly injuries, requires more detailed reporting of the causes of trauma in serious and fatal vehicular accidents.

THE NAVY — 1957

"The Navy will add six warships and five other vessels to the fleet during fiscal '57, but manpower will be decreased.

"Slated to end fiscal '56 on 30 June with 405 warships, the Navy has won Administration approval for 411 warships a year later and for 594 other ships—a total of 1105, compared with 944 planned for the end of the present fiscal year.

"The Navy will have the same number of carrier air groups, 17, and carrier anti-submarine squadrons, 31, at the start and end of fiscal '57.

"On the personnel side, newly announced plans will show the Navy beginning the year of 1 July with 662,744 officers and men, and ending the 12 month-period with 662,175.

"At the end of fiscal '57, the Navy foresees a strength level of 72,800 officers and 584,200 enlisted men, identical figures with those at the beginning of the year."

MINOR REFRACTIVE ERRORS VERSUS DEPTH PERCEPTION

BUTHER L. NEWMAN, *Lieutenant (junior grade), MSC, USN*

GOOD DEPTH perception is important to everyone, but as was pointed out when the visual screening profiles of a group of Overhaul and Repair Department inspectors at this air station were being reviewed, some who are in technical trades and professions need to excel in this particular visual skill. Because screening on depth perception was included in the routine checks along with far and near point acuity, far and near point muscle balance, and color perception, some interesting data were compiled. This is especially true of the findings on 17 men who initially failed the depth perception screening, but who passed on a second trial, after having been refracted and given a lens prescription (table 1). These data substantiate the opinion that refractive error and bad depth perception go hand in hand.

In the phenomenon of depth perception, many factors are combined before a final estimation of depth is accomplished. Although the time element involved in making an estimation is only a split second, a combined reaction to various stimuli has taken place in the observer's nervous system. For purposes of discussion, these stimuli can be called factors, and the factors classified as adjunctive (depending on the relative comparison of one outside object to another) and basic (depending solely on the observer's perception apparatus and the object under estimation). Adjunctive factors are: comparison of retinal image sizes of two familiar objects; motion parallax (*i. e.*, the apparent motion of objects within the visual field surrounding the object of fixation that is caused by movement on the part of the observer); linear perspective; and familiarity with the effects of atmospheric conditions on the appearance of distant objects. This last factor might be referred to as aerial image. Add to this the factor of accommodation (or range of focusing), and you have a fairly complete list of adjunctive factors affecting depth perception that are available to either one- or two-eyed individuals.

Since the best depth perception depends on factors which are available only to persons with binocular vision, and since this

article is wholly concerned with binocular subjects, let us consider what takes place in the case of such an observer who is hampered in estimating depth by some slight anomaly in the form of a minor refractive error in one or both eyes. The foremost factor in making a depth estimate that is affected by a refractive error is binocular parallax, by means of which the two eyes working in a binocular pattern can discern the movement of an object either toward or away from the object of fixation. This is possible because binocular subjects have available to their perception apparatus overlapping retinal fields, semidecussation of optic nerve fibers, corresponding points, and conjugate movements of the eyes. Unless visual acuity is approximately equal in the two eyes, the foregoing physiologic factors will not be nearly so effective in helping to make accurate depth estimates. Just what physiochemical, neurophysiologic, or gross anatomic changes are responsible for the phenomena that refractionists call refractive errors is still open for research, but since this article is reporting only the effects of refractive errors on depth perception, I will not attempt further discussion of the physiologic processes involved.

Of about 400 inspectors examined, 17 men ranging from 29 to 48 years of age were found to have substandard depth perception; yet their failing of the depth test on routine visual screening was the first intimation that anything was amiss in their visual apparatus. None would admit to having any subjective complaint with respect to visual acuity or visual discomfort. The fact that these 17 men would be able to pass every other screening test, so long as depth perception was not checked, points up the extreme desirability of including such a test in the routine visual screening of any age or occupational group. Were it not for their having failed on the depth check, these men would not have attained the increased visual efficiency which their subsequent lens prescription afforded them.

These 17 men were not the only ones whose scores on depth screening were below the standard set for Overhaul and Repair inspectors, but they were the only ones of these who had no objective or subjective sign of any visual defect other than faulty depth perception. That the percentage of the entire group examined who failed their depth screening was low was because even prior to the inclusion of the depth check in the screening routine, the men were periodically rescreened every six months, and appropriate changes were made in their lens prescriptions. Therefore, each could be considered to be at his peak efficiency insofar as visual acuity was concerned.

All but one of the 17 men had unaided monocular visual acuity of 20/20, the single exception having 20/20 O.D. and 20/40 O.S. There seemed to be no relationship among the 17 in regard to

These 17 men were not the only ones whose scores on depth screening were below the standard set for Overhaul and Repair inspectors, but they were the only ones of these who had no objective or subjective sign of any visual defect other than faulty depth perception. That the percentage of the entire group examined who failed their depth screening was low was because even prior to the inclusion of the depth check in the screening routine, the men were periodically rescreened every six months, and appropriate changes were made in their lens prescriptions. Therefore, each could be considered to be at his peak efficiency insofar as visual acuity was concerned.

All but one of the 17 men had unaided monocular visual acuity of 20/20, the single exception having 20/20 O.D. and 20/40 O.S. There seemed to be no relationship among the 17 in regard to

the type of refractive correction needed, except that none were myopic. Some had simple hyperopia; others had variable types of astigmatism. One of the group required a short period of supervised orthoptics, in addition to his lens correction, to remedy a moderate amount of excessive exophoria. Upon rescreening after this treatment, he was able to pass the depth check. Age did not seem to have any significant relationship to failure on the depth check. The average age was 38 years only because there is little turnover in personnel among this particular group, with the natural consequence that the same group tends to be on the same job for a number of years.

SUMMARY AND CONCLUSIONS

The visual skill of depth perception can hardly be overstressed, and it is of paramount importance to include a depth check in every visual screening routine. Otherwise, the screening cannot be considered all-inclusive for evaluation purposes. This is illustrated by the finding of 17 men, among about 400 examined, who would be considered acceptable in any visual screening check were it not for their inability to exhibit a passable performance in depth perception. It appears important in the light of this experience that refractionists give careful consideration to any refractive error, no matter how small, as being a potential factor in causing a substantial decrease in visual efficiency.

GLAUCOMA PREVALENCE

"The National Society for the Prevention of Blindness estimates that approximately one million Americans have undiagnosed chronic simple glaucoma and states that every general practitioner should assume that one in 50 of his patients who are over 40 years of age probably has this disease." Early detection and treatment result in a favorable prognosis.

Malignant Palatal Lymphoma Involving the Periodontium

JAMES E. CHIPPS, *Lieutenant Colonel, DC, USA*

C. JULES ROMINGER, *M. D.*

WILLIAM D. STANCUTT, *M. D.*

THE radiosensitivity of localized lesions in malignant lymphoma is well known. However, if there has been spread of the lesion to adjacent structures, usually some distant metastasis also exists and the benefits of local therapy are but short-lived.

The following case is of interest because the local involvement was marked, but there is no evidence of generalized disease or local recurrence 2½ years after irradiation therapy.

CASE REPORT

A 26-year-old man was returned from overseas with an ulcerating tumor of the oronasal structures, centering in the palate, which had been diagnosed as malignant lymphoma by biopsy.

History. Frequent episodes of acute nasal obstruction and sinusitis had occurred since the patient was 12 years old. There had been a sudden onset of left-sided earache and tinnitus 10 months before admission. The maxillary sinuses had been irrigated three months before, producing much purulent, foul-smelling material. Shortly afterwards, pain and swelling began in the roof of the mouth, and an ulcer appeared in the soft palate. The patient was hospitalized and treated with antibiotics. The swelling and ulcer continued to enlarge, and biopsies were obtained on separate occasions from the margin of the ulcer, the nasopharynx, and the tip of the inferior turbinate. Pending the results of the biopsies, cortisone and corticotropin (ACTH) were employed but without effect. A report of malignant lymphoma was obtained, and the patient was transferred from the overseas hospital to the zone of interior.

The transfer was completed on 5 October 1953. In the preceding few days, the patient had noted a rapid increase in the size of the ulcer, the swelling of the soft palate, and symptoms of nasal obstruction. In the preceding three months, there had been a 25-lb weight loss, which he attributed to an inability to masticate and a loss of appetite because of the foul-smelling oral ulcer.

1. The patient appeared chronically ill. A tumor mass of the nasopharynx and partially occluded the oropharynx so respiration by mouth was slightly labored. The tumor mass measured approximately 9 by 5 cm, and a central area of ulceration measured by 2 cm. The lesion involved the entire hard and soft palate (figs. 1 and 2). The uvula was enlarged to twice its normal size. There was

Figure 1. Anterior portion of ulcerative lesion, hard palate.

Figure 2. Posterior portion of ulcerative lesion, soft palate and oral pharynx.

tumorous extension to the left tonsil and the upper pole of the right tonsil. A communication through the necrotic ulcer between the mouth and the floor of the right nasal cavity could be demonstrated by probe. All maxillary teeth were slightly mobile, although the marginal gingivae were at normal levels and the epithelial attachments had not receded. Nodes were palpable and tender deep to the mandibular angles bilaterally.

Radiographs showed destruction of the medial portion of the hard palate, opacity of the maxillary sinuses, and a polyp in the right frontal sinus.

Radiographs of the chest were normal, and the rest of the physical examination was not significant.

Treatment. The patient was presented to the hospital's tumor board. Irradiation therapy after extraction of the maxillary teeth was recommended.

Under general anesthesia on 6 October, a biopsy specimen was obtained from the edge of the palatal ulcer, and the dental extractions were accomplished. Although no attempt was made to include surrounding blocks of the maxillary bone in the routine forceps removal of the teeth, spongy white material which contained bony spicules clung to the apical half of each tooth as it was removed. An alveolectomy sufficiently extensive to permit approximation of the mucoperiosteal edges across the sockets was performed as a protective measure against the effects of irradiation.

Microscopically, the biopsy specimen from the palate (fig. 3) showed masses of atypical lymphocytes within the intratrabecular areas of cancellous bone. These lymphocytes presented a monotonous uniformity. There were no giant reticulo-endothelial cells. There was erosion of bone. A few fat cells were seen, but most of the fatty tissue was obliterated by the infiltrating tumor cells. A diagnosis of lymphosarcoma was made.

One of the extracted teeth with attached tissue was decalcified and sectioned. There was a diffuse infiltration of atypical lymphocytes in the tissue adjacent to the tooth root (fig. 4). Fragments of alveolar bone showed compression and erosion. Erosion of the cementum was seen in one area.

Irradiation therapy was accomplished between 7 October and 18 November, using the following factors: 200 kv, 20 ma, 50 cm target skin distance, Thoraeus filter half-value layer 1.95 mm Cu. Multiple portals were employed which encompassed the entire nasopharynx, all of the paranasal sinuses, and the lymph nodes in the upper cervical regions (fig. 5). A tumor dose of 3,000 roentgens was administered to all of these regions. Following this, additional treatment was delivered to residual tumor in the palate using a peroral lead cone and the following factors: 200 kv, 20 ma, 40 cm target skin distance, 0.5 mm plus

Figure 3. Microscopic section from hard palate showing atypical lymphocytes and bone erosion. ($\times 100$)

1.0 mm Al filter half-value layer 0.9 mm Cu, 1,500 r (in air). This raised the total tumor dose in the palate to 4,500 roentgens.

The patient tolerated this course of treatment well. The eyes and the oral commissures were protected by 4 mm of lead during the treatments. A second-degree erythema developed externally (fig. 6), and an ulcerative reaction developed in the palate. As the tumor regressed, there was a residual oronasal fistula at the junction of the hard and soft palate (fig. 7). By 14 December, all reactions had healed. There were no enlarged lymph nodes in the neck, and there was no evidence of residual neoplasia. The patient had gained 20 pounds during the treatment, and his general condition was good.

Course. A maxillary denture was constructed, which also served as a temporary obturator for the oronasal fistula. The patient was given physical disability discharge from the Army in April 1954 and subsequently observed at a Veterans Administration hospital at regular intervals.

Except for a chronic postnasal discharge there were no positive findings until January 1955, when radiographs disclosed a possible mass in the left maxillary sinus. A Caldwell-Luc procedure was performed on 21 January. The maxillary sinus was found to be free of masses. Multiple biopsies were performed, which revealed chronic

sinusitis but no evidence of recurrence of malignancy. Following this operation, an oroantral fistula developed. After one unsuccessful attempt at closure, the fistula was surgically closed in December. No recurrent malignancy was noted in either procedure.

In March 1956, a routine follow-up examination was again negative for recurrent malignancy. Examination at regular intervals will continue.

COMMENT

The lymphatics of the palate and the nasopharynx are the possible sites of origin in many reported cases of malignant lymphoma, and frequently there is a history of prolonged paranasal infection. When bone is involved in lymphosarcoma, such involvement is indicative of spreading rather than early disease.

In this case, the spread of disease was manifested by the perforation of the hard palate, loosening of teeth after replacement of the normal periodontium by tumor, fixation of the soft palate, fixation of the tonsils, enlargement of the upper cervical nodes, occlusion of the nasopharynx by a mass, and radiographic evidence of paranasal sinus involvement. Considering this regional spread and the nature of lymphosarcoma, a modified program of therapy directed at relief of symptoms was considered but rejected in favor of the attempt at curative therapy. The apparent absence of local recurrence or generalized disease after $2\frac{1}{2}$ years is encouraging.

Volkman's Contracture of the Lower Extremity

A Complication of Patellar Tendon Transplantation

WALTER R. MILLER, *Captain, MC, USN*

WHENEVER an untoward incident occurs during a surgical procedure, there is an understandable reticence on the part of the surgeon to publish the case. If such information is given proper dissemination, however, it may assist in the recognition of premonitory signs in other patients, and possibly in the amelioration of residual damage. The following is such a case.

CASE REPORT

A 17-year-old girl student, seen as an outpatient, complained of falling several times a week because of bilaterally dislocating patellas. This had been occurring for a number of years, but recently had become more frequent and, in view of her age, more embarrassing. Examination corroborated the diagnosis. The left patella could be completely dislocated off the lateral femoral condyle when the knee was in approximately 40° of flexion. The right patella could be subluxed only. Roentgenograms confirmed the suspicion that both lateral condyles were lower in profile than normal.

Transplantation of a bone block including the left patellar insertion was performed on 28 February 1952. The block was moved medially and slightly distally, and secured with a stainless steel screw. The usual freeing of the lateral aspect of the extensor mechanism was done, and followed by reefing along its medial border. In spite of having been dislocated frequently, the patella, although somewhat smaller than normal, presented an articular surface covered with normal, glistening cartilage. It rode in an accessory groove in the lateral condyle completely apart from the intercondylar notch. The medial femoral condyle was hardly recognizable as such. It was deformed and although it was partially covered with cartilage, the cartilage was covered with synovial membrane.

The completely uneventful procedure, which required 1 hour and 10 minutes from initial incision to skin closure, was accomplished under spinal anesthesia and with a pneumatic tourniquet of the Campbell-

From U. S. Naval Hospital, San Diego, Calif.

Boyd type inflated to 480. The tourniquet was applied to the thigh but not inflated until after preparation of the skin, and spiral application of an Esmarch rubber bandage. Thus the tourniquet pressure began no more than five minutes prior to the incision. Following the operation, a long leg cast was applied over ample sterile sheet wadding, after which the tourniquet was deflated and removed. Total tourniquet time was slightly less than 1 hour and 30 minutes. Good color and warmth returned to the toes immediately. The patient was taken to the ward in good condition and the casted leg was elevated on several pillows. About eight hours postoperatively, the surgeon was called by the surgical watch officer, who stated that the patient was having some pain in the leg but that the color and temperature of the toes were satisfactory. The surgeon recommended that the cast be split and spread slightly. There were no more phone calls that night, and it was believed that all was satisfactory.

The following morning at 1000 the patient was writhing with pain, although her operated leg from which the cast had been completely removed appeared essentially normal. Color of the leg and foot was good, and the temperature was equal to that of the other leg. Capillary return time in the toes was good, but neither posterior tibial nor dorsalis pedis pulsations could be felt and no oscillations were obtained by oscillometer except above mid thigh, where they were normal. The calf muscles were firm and somewhat tender, and the foot was in moderate equinus. The foot could not be dorsiflexed even to neutral, and much discomfort was caused by the attempt. The patient was quite clear in stating that her severe pain was in the entire leg from the site of the tourniquet distally. The tourniquet site in mid thigh was very tender, more so than any other area.

Hypesthesia to anesthesia started 4 inches below the knee joint over the lateral aspect of the leg and about 8 inches below the knee joint on the medial side, the two areas joining anteriorly about 7 inches above the ankle joint. The skin over the calf and foot was almost completely anesthetic.

Consultation with the neurosurgeon and the anesthetist resulted in the use of continuous caudal block with Pontocaine (brand of tetracaine hydrochloride). This promptly relieved pain and caused the leg to be somewhat warmer than the unoperated leg. The patient also volunteered: "The leg feels like it's mine now down to just above the ankle." An oxygen tent used only for cooling was placed over the leg and the temperature maintained between 75° and 80°F.

On the following day consultation among the chiefs of the orthopedic surgical, general surgical, and neurosurgical services and two civilian consultants (neurosurgery and orthopedics) resulted in recommendation for lumbar sympathectomy. Following this procedure the leg was cradled in cotton in balanced suspension. The operative incision was unremarkable. The leg, including the heel, was warm, but the foot remained cool and pulseless although capillary return was adequate. Pain was reduced to moderate discomfort.

On about the third day, the calf muscles had reached a maximum of almost woody hardness and the picture of Volkmann's ischemic contracture was well developed. A small, quarter-sized area of blackened skin appeared on the heel, together with a small, blistered area overlying the tendinomuscular junction of the Achilles tendon. These both disappeared during the next two weeks.

In spite of gentle but persistent physiotherapy, followed later by a low leg brace with dorsiflexing foot spring, the foot over the next three months assumed a position of equinovarus of moderate severity (30° of equinus). The operative wound healed without event. The patient could do a straight-leg raise with the knee locked in full extension in $4\frac{1}{2}$ weeks postoperatively, and the patella was felt to ride medially in a normal position. Six months following operation she had a full range of motion in the operated knee, without effusion. The foot could be voluntarily dorsiflexed to about 20° below neutral and everted to neutral. There was gross tightness and some residual induration in the posterior calf muscles; however, there was evidence of slight return of function in these. The level of hypesthesia had moved distally at least 5 inches, but the entire foot was still anesthetic. Physiotherapy, including heel cord stretching, was continued and the patient was wearing a brace part time while waiting until surgical correction of the foot deformity would be indicated.

DISCUSSION

The contracture I have described followed a relatively simple orthopedic operation on the anterior aspect of the leg performed under a properly applied pneumatic tourniquet. Search of the English literature revealed no other case of Volkmann's contracture of the leg following operation on the lower extremity, aside from a number of cases occurring as a complication of fracture of the femur. The condition is mentioned as a possibility by several authors while discussing the problem in the upper extremity.

To review in retrospect the situation as it confronted the operator at 10 o'clock on the morning following the operation, it was clear that splitting of the cast had not relieved the patient. Although she had required only two hypodermic injections of 10 mg of morphine and 60 mg of codeine during the first 20 hours postoperatively, she had complained of severe pain in the leg and of numbness in the foot and toes to such an extent that the entire cast had been removed in the early hours of the morning. At this time, according to the nurse's notes, "the toes and instep were blotched and blue." These were premonitory signs that could have been recognized and reported to the responsible surgeon. Whether earlier application of methods to reduce vascular spasm would have been effective in averting the residual damage will remain unknown, but it seems likely.

Much difference of opinion exists concerning when to explore the vessels in this condition. It was the opinion of those consulted in this case that since no trauma other than broadly distributed pressure from a pneumatic tourniquet had been inflicted on neurovascular structures, adequate blocking of the sympathetic outflow would be as effective or more so than operation in relieving vascular spasm. This view is supported by the report of Thomson and Mahoney¹ who state: "It seems significant that of all cases treated with sympathetic block (spinal anesthesia) only one was a failure and six were cured—muscle decompression with or without arterial exploration has proved to be of no value."

The opinion of Myerding² is of significance in cases that may become the subject for litigation: "Volkmann's ischemic contracture may result from injury when bandages, splints or casts of plaster of paris have not been used; this is a highly important fact, from a medicolegal point of view . . . I should like to emphasize again the great importance of the fact that Volkmann's ischemic contracture may result when there is no fracture and when no splint, bandage or cast has been applied."

SUMMARY

A case of Volkmann's contracture of the lower extremity following a relatively simple orthopedic procedure is presented. No report of a similar case could be found on search of the English literature. Early recognition of premonitory signs and symptoms of this complication is of the greatest importance, so that early treatment can be instituted and residual damage be reduced to a minimum.

Situs Inversus of Gastro-intestinal Tract

Complication by Partial High Intestinal Obstruction

RICHARD R. PICHEL WARNER, *Captain, USAF (MC)*

TRANSPOSITION of the stomach alone, or with situs inversus of all the infradiaphragmatic viscera, is ordinarily asymptomatic although sometimes associated with eventration of the right diaphragm.¹ Situs inversus of the intra-abdominal organs occurs once in every 6,000 to 8,000 individuals² and is more common than partial transposition or incomplete rotation of a portion of the gastro-intestinal tract. The latter condition, however, frequently produces symptoms, and the majority of such patients are brought to medical attention during early infancy. Occasionally an individual who has symptoms resulting from anomalous rotation of a portion of the gastro-intestinal tract will not seek medical attention until early adulthood because his symptoms may have been mild, although chronic. Only in recent years has it been appreciated that such congenital anomalies need not produce clinical manifestations until early adult life.^{3,4} Since the majority of military personnel are in this age category, the military physician should be acquainted with the symptoms and realize that such conditions may occur in young adults, and are not exclusively confined to infants and children.

EMBRYOLOGY

In order to understand the genesis of the group of conditions resulting from faulty rotation of the gastro-intestinal tract, it is necessary to have an understanding of the main features of the process whereby the gastro-intestinal tract attains its final asymmetrical arrangement.^{5,6}

The digestive tract of the embryo is divided into a foregut, midgut, and hindgut. The midgut extends from the third portion of the duodenum to the midtransverse colon. Distal to this area is hindgut, and proximal to it is foregut.

At the fourth week of fetal life, the primitive gut hangs in the midline supported by a common dorsal mesentery. A fusiform dilatation, the future stomach, appears, and just below this the liver diverticulum and the bud that gives rise to the pancreas develop. The primitive stomach becomes further dilated so that

From 3750th U. S. Air Force Hospital, Wichita Falls, Tex.

its right surface is directed backward with the greater curvature facing downward and to the left. Due to this rotation, the liver and pancreas are carried from the midline to their respective final positions. If the stomach and descending portion of the duodenum rotate to just the opposite position from that described, the liver, pancreas, and spleen will then be carried along and be situated in such a way that they present a mirror image of their normal positioning; *i. e.*, situs inversus.

While the development and rotation of these portions and growths from the foregut are occurring, development and migration of the midgut is also underway. The midgut is divided into a prearterial portion, which extends from the third portion of the duodenum to the vitelline duct, and the postarterial portion, which extends from the vitelline duct (or Meckel's diverticulum) to the midtransverse colon. Between the sixth and tenth weeks the gut grows too rapidly for the celomic cavity to accommodate it. This results in the protrusion of a part of the midgut into the base of the umbilical cord (fig. 1A). By the tenth week, however, the peritoneal cavity becomes large enough to contain this portion of the midgut, and it is withdrawn from the base of the umbilical cord. As it enters the abdomen, it rotates in a counterclockwise direction so that the postarterial portion of the midgut (the segment from vitelline duct to midtransverse colon) is situated in the left side of the abdomen. This anticlockwise rotation continues after the midgut is entirely within the abdomen so that the cecum, which initially is in the left midabdomen, migrates to the left epigastrium and thence to the right epigastrium (fig. 1B), and finally swings around to its adult position in the right lower quadrant. The cecum and ascending colon then acquire their peritoneal reflections and attachments in the right side of the abdomen. At the same time, the small bowel, which also has been rotated in a counterclockwise direction, becomes firmly attached to the posterior abdominal wall by its mesentery.

Figure 1. Embryology. (A) Protrusion of a portion of the midgut into the base of the umbilical cord at 6 to 10 weeks' stage of development. (B) Midgut has re-entered abdomen at 10 to 12 weeks' stage of development and has undergone partial counterclockwise rotation so that cecum lies in right upper quadrant. This rotation will normally continue and will carry the cecum to the right lower quadrant, its final position.

1-Superior mesenteric
artery
2-Umbilical orifice

3-Vitelline duct
4-Cecum
5-Descending colon

midgut may not occur. Most of the midgut, and particularly the postarterial portion, may still go to the left side of the peritoneal cavity upon entering the abdomen, but then the process of counterclockwise rotation may not go to completion, perhaps because of the large liver mass located in the left upper quadrant. This may then result in the cecum and most of the colon being located in the left side of the abdomen; the cecum may be mobile, and there may also be nonfusion of the mesentery of the midgut so that the small bowel hangs on a pedicle of the superior mesenteric artery.

Therefore, three types of abnormalities may occur to the midgut in association with or without situs inversus of the stomach and liver: (1) return of the midgut to the abdomen without any rotation;

2 inches in height and weighed 170 pounds. His usual weight had been 195 pounds. Vital signs were normal. Hydration was only fair. There was a prominent sternum and a slight pigeon-breast type of sternal deformity. The remainder of the physical examination disclosed no significant abnormalities.

Laboratory Findings. Peripheral blood studies at the time of admission revealed a red blood cell count of 3.7 million per μ l; hemoglobin was 11 g per 100 ml; hematocrit, 52.5 ml per 100 ml; reticulocyte count, 1.1 per cent; and white blood cell count, 13,400 per μ l with a slight shift to the left. The stool contained traces of occult blood. Urinalysis showed no abnormalities. Determinations of the fasting blood sugar, serum chlorides, and basal metabolic rate all yielded values within normal limits. The gastric contents after fasting contained 65° of free acid, and after histamine, 90° were present. An electrocardiogram showed no significant abnormalities. A roentgenogram of the chest was normal. The heart was in its normal position on the left. No defects in the diaphragms were noted. An upper gastro-intestinal series demonstrated situs inversus of the abdominal organs and an anomalous course of the duodenum. There was spasm of the pylorus and the duodenal bulb could not be well outlined. No deformity or ulcer crater could be seen. Several more upper gastro-intestinal series and roentgenograms of the small bowel were taken with the intent of studying the anomalous duodenum in detail. Barium was introduced by Levin tube in one of these studies. The duodenal bulb was well visualized and showed no deformity or ulceration. The anomalous course of the duodenum was well demonstrated (fig. 2), and considerable dilatation of the bulb and first portion of the duodenum was seen. A point of obstruction was visualized low in the descending limb of the duodenum (fig. 3). At this point, the transverse mucosal folds were converted into vertical striations. There was delayed passage of barium past this point. The picture was felt to represent partial obstruction due to extrinsic pressure as might be caused by a mesenteric band. Beyond this area, there was a reversed loop of the duodenum before it passed into the proximal jejunum, which went high and posteriorly on the right side of the abdomen. The cecum was low on the left side of the abdomen. A congenital anomaly of the lumbar spine consisting of failure of segmentation of L5 and S1 was present. An intravenous pyelogram showed two normal kidneys and ureters.

Course in Hospital. The patient was initially maintained on a nutritious liquid diet and antacids. After two weeks, symptoms of obstruction disappeared and he was allowed a more nearly regular diet. His work-up was completed, and on 9 June 1955 he was operated on.*

At operation, as seen on the roentgenograms, his abdominal viscera were completely transposed from left to right in a mirror image of the normal arrangement. The cecum was completely mobile and the small

*Operation was performed by Capt. Gilbert L. Chamberlin, USAF (MC).

Figure 2. Roentgenogram demonstrating situs inversus of the stomach and anomalous course of duodenum.

intestine's mesentery was attached to the posterior abdominal wall for only eight centimeters. The appendix contained several fecaliths. The jejunum and ileum were normal as was the ligament of Treitz. The duodenum was elongated to about 15 inches and was enveloped in peritoneal folds, which at the most dependent portion of the duodenum had kinked this loop of gut in a sharp 180° angle. This point of sharply angulated gut was just below the attachment of the duodenum to the pancreas. From this point, the duodenum crossed itself, ran laterally upward and back across itself again, and then posteriorly to the superior mesenteric artery to reach the ligament of Treitz. Two normal kidneys were present, but a right retroperitoneal mass was noted and proved to be an accessory kidney. The duodenum was mobilized and its kinked dependent portion was straightened out by freeing it from the enveloping mesenteric folds. It was felt that this would be sufficient to relieve the patient's symptoms of recurrent partial intestinal obstruction. The appendix was also removed.

Postoperatively, the patient's convalescence was entirely uneventful, and three weeks after surgery he was returned to duty. When seen three months later, he was entirely free of gastro-intestinal symptoms and eating a regular diet.

Figure 3. Roentgenogram demonstrating considerable dilatation of the duodenal bulb and first portion of the duodenum, with point of partial obstruction in descending limb of duodenum just proximal to sharp angulation.

It was believed at the time of operation that, although incomplete, the attachment of the small intestine's mesentery to the posterior abdominal wall was sufficient to render the possibility of volvulus unlikely. Therefore, no attempt was made to immobilize the small bowel by further attaching its mesentery. The increased incidence of duodenal ulcer in association with partial obstruction at the duodenum due to congenital bands or adhesions¹ was appreciated. Hence, roentgenographic studies were meticulously performed in the search for an ulcer. Such ulcers are felt to be due in large part to stasis. Our patient may have had such an ulcer in the past or at the time of admission, and its bleeding would explain the mild anemia and occult blood in the stools found when he was hospitalized. Such an ulcer at the time of admission could have been a very superficial one and could have healed prior to operation. In such ulcer cases, since stasis is the major causative factor, the surgical relief of the duodenal obstruction is usually sufficient to result in cure.

THE FOUR STAGES OF KNOWLEDGE

"Where are we in our efforts to understand arteriosclerosis? Well, certainly not very far. Discovery in general can, I think, be divided into four stages. The first is the period of uncoordinated fact collecting—the naturalist or "butterfly net" period. This is the period of magnificent indifference; in it lie the seeds of discovery but the inner structure is barely discernible. The second is the period of controversy—the "rhubarb stage" of the ball game. This stage is often called one of "scientific controversy" to make it sound less like the rhubarb that it really is. It has the merit that there is probably something worth arguing about if this stage is reached. It is healthy so long as young investigators understand its nature and not take it, or themselves, too seriously. The third is the period of definition and clarification—the "white of an egg stage" because someone clarifies the problem by precipitating the irrelevant sediment. The fourth and last is the period of solution or fruition—the "bravo stage" in which everyone, or nearly everyone, agrees, applauds and goes home and from then on nobody does much more about it, except in some rare cases, collects royalties.

"I think you will agree that research in arteriosclerosis stands about half way between the first and second stages."

A MESSAGE FROM THE A. M. A.

A recently published letter from an anonymous captain received wide circulation among military personnel. The correspondent attempted to establish that the basic cause of the acute shortage of doctors in the armed services is that there are simply not enough available physicians in this country. To support his opinion, the captain accused the American Medical Association of limiting the number of medical schools as well as the number of licensed physicians. Specifically, he charged that (1) the A. M. A. began a policy 50 years ago of closing down medical schools; (2) only 1 out of every 10 or 20 applicants is admitted to a medical school; and (3) the A. M. A. started a policy of refusing to permit Americans who are graduates of European medical schools to take state medical board examinations.

Statements like this are not new, and unfortunately they have been repeatedly made in public print. Are they fact or fiction? Well, let's examine the record and see.

As to the first charge, *the American Medical Association has never closed any medical school*. In fact, it has neither the authority nor the desire to control the growth of medical schools. Some 56 years ago, a report on the unsavory quality of medical education in the United States was published as a result of a study spearheaded by Dr. Abraham Flexner. The report clearly revealed that only about one third of the schools then in existence were offering a satisfactory medical education adequate to meet the needs of that period. The report shocked reputable medical educators, and their actions brought speedy results. A vigorous house cleaning ultimately wiped out about two hundred fly-by-night schools which were either diploma mills or had facilities, personnel, or financing inadequate to offer a medical education suitable for that period. From 1910 until about 1928, medical schools were classified as A, B, or C in terms of their over-all potentialities; B or C schools either improved or closed their doors. This type of classification was discontinued in 1928, and since that time medical schools have been approved or not approved.

The American Medical Association Council on Medical Education and Hospitals has worked closely with the Association of American Medical Colleges in constant efforts to assist in developing and maintaining sound standards of medical education

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.—
Editor.

in the United States in the interests of the American public, which the graduates of our medical schools must serve. These two organizations have exerted great influence in medical education. They have co-operated in stimulating and encouraging new medical schools, and have assisted in the improvement of those in existence by establishing sound, basic essentials of medical education, as well as by consultations, advice, and survey evaluation.

The number of approved medical schools in the United States increased from 66 in 1910 to 81 in 1955, a growth of 22.7 per cent. On the basis of new schools now under development, the number will have increased 30 per cent by 1960. In 1955, there were 28,583 students enrolled in medical schools as compared with 12,530 in 1910. The number of physicians graduated from approved medical schools since 1910 has far outstripped the growth of the over-all population of the United States. While our general population was increasing 80 per cent, the supply of doctors increased 120 per cent. Today, we have not only more doctors, but far better care than a generation or two ago. Physicians now treat a great many more patients and treat them more efficiently.

The second charge is likewise incorrect and not supported by the facts. Simple arithmetic establishes that *over half of all applicants were accepted into medical schools in 1953-1954 and in succeeding years*. The exact ratio of admissions to the number of applicants for 1953-1954 was 1 to 1.97, or 7,749 admissions out of a total of 14,678 applicants; for 1954-1955 it was 1 to 1.93, or 7,556 admissions out of a total of 14,538 applicants. Several years ago, publicity was given to the number of applications filed rather than to the total number of applicants filing them. This was incorrectly interpreted to mean that only 1 out of every 10 or 20 applicants is admitted to a medical school. The fact is that each applicant usually applies to some 2 to 4 or 5 medical schools. This means, of course, that the number of applications filed represents many times the number of people who are actually applying for admission to a medical school. For example, in 1953-1954 there were 48,556 applications for admission to medical schools, made by 14,678 individuals. Each applicant filed an average of 3.3 applications. Even at the peak period of admission to medical schools in 1948-1949, when large numbers of young men were being released from military service, the ratio of applicants to admissions was never higher than 3.6 to 1.

The third charge is a fallacy. By state statutes, it is the function and authority of the individual states to determine who shall practice within their borders, and to maintain high standards of medical practice in accordance with their respective rules and

regulations. The State Boards of Medical Examiners are independent agencies, and *the licensing in each state is done on the basis of the individual medical practice acts of the states concerned and the determinations of the various individual licensing bodies.* There are 20 medical licensing boards that permit licensure of foreign-trained physicians. On the other hand, foreign-trained physicians are not eligible for licensure by 12 boards. Special requirements for foreign-trained physicians are specified by 18 boards, while 16 boards have varying exemptions. In the final analysis, medical licensure in the United States is a "sovereign state right" that is entirely under the jurisdiction of the governments of the individual states.

The captain's suggestion for the creation of a medical academy to produce medical officers for the Armed Forces is not new. This idea has been carefully considered for a number of years by Congress, the military services, the medical profession, and groups of medical educators. All who have looked into the problem agree that, if the services are to produce their own physicians, it is far better and cheaper to subsidize the education of medical students in existing medical schools than for the Federal government to create, equip, and staff a separate medical academy. Furthermore, all groups agree that the present diversification in background and training of medical officers who have graduated from a number of different medical schools is a distinct advantage to military medicine.

Based on these decisions, the military services recommended legislation to the last Congress that would have permitted the subsidization of medical students under contract to become career military medical officers upon the completion of their training. This recommendation had the whole-hearted support of the medical profession.

Before Congress had completed final action on the proposal, however, the military services found it possible to establish a program of subsidizing the training of selected senior medical students in return for commitments of military service. This program is now in operation with the full support of the medical profession and medical educators. Studies are currently under way to determine the feasibility of extending this program to include junior medical students as well.

Programs of this type, together with the recently enacted career incentive bill for medical officers, should prove of great assistance in solving the basic problem.

EMINENT ARMY UROLOGIST DIES

Colonel James C. Kimbrough, MC, USA (Ret.), age 68, died on 19 August 1956 at Walter Reed Army Hospital, where he had served for the past 10 years.

From 1946 to 1953, he was chief of the hospital's Urology Service. In August 1953, upon retiring from the U.S. Army after 36 years of service, he was designated by an Act of Congress as consultant in urology to Walter Reed Army Medical Center, "... in recognition of the outstanding service and contribution made to the science of medicine and surgery... and to provide that his mature professional judgment and long experience may continue to remain available to the public service...."

A native of Madisonville, Tenn., he was graduated from Hiwassa College and from Vanderbilt University School of Medicine before entering the military medical service in July 1917. Since 1921, he served almost exclusively as chief urologist at various Army hospitals, including four duty tours at Walter Reed. He was also Chief of the Professional Services Division in the Office of the Chief Surgeon, European Theater of Operations, from 1942 to 1945.

In World War I, Colonel Kimbrough received the Purple Heart award, and a Meritorious Service Citation signed by General of the Armies John

J. Pershing. In World War II, he was awarded the Legion of Merit and the Bronze Star Medal. In 1952, he was awarded a plaque by the American Urological Association, of which he was a member, in recognition of his "contributions to the advancement of science and practice of urology" and for his "efforts in promoting pleasant working relations between civilian and military medicine," and in 1955 he was elected president of that association's Mid-Atlantic Section, the first time in the association's history that a former Army officer had held the position. Since his death the annual postgraduate refresher course in urology at Walter Reed has been named in his honor.

FIRST INTERNATIONAL CONGRESS OF NEUROLOGICAL SCIENCES

The First International Congress of Neurological Sciences will be held in Brussels, Belgium, 21-28 July 1957. This Congress is the first integrated international convention of all independent international congresses of several neurological disciplines. Meeting simultaneously in Brussels under the new co-ordinated program are Sixth International Neurological Congress, Fourth International Congress of Electroencephalography and Clinical Neurophysiology, Third International Congress of Neuropathology, First International Congress of Neurological Surgery, Third Meeting of the International League against Epilepsy, and Second Symposium Neuroradiologicum.

The scientific program will highlight two major symposia of common interest to the Congress: Extrapyrarnidal Disease, by Professor Raymond Garcin of Paris, and the Significance and Interpretation of Modifications of the Conscious State, by Sir Geoffrey Jefferson of London. Special interest symposia will include Multiple Sclerosis, under the Chairmanship of Professor H. Houston Merritt of New York.

Further information may be obtained from Dr. Pearce Bailey, Secretary, Committee for the United States of the Sixth International Neurological Congress, National Institutes of Health, Bethesda 14, Md.

DEATH

ALTEE, Miriam Elizabeth, Lieutenant, NC, USN, of Columbia, S. C.; Chief Nurse at U. S. Naval Air Station, Norfolk, Va.; graduated from the Petersburg Hospital School of Nursing, Petersburg, Va., 12 August 1937; appointed, Nurse, in the U. S. Navy and ordered to active duty 6 May 1940; died 24 August 1956, age 43, at the U. S. Naval Hospital, Portsmouth, Va., of metastatic carcinoma of the vertebrae.

Promotions of Officers

The following officers of the military medical services on active duty in the Army, Navy, and Air Force have recently received temporary promotions to the rank indicated.

ANNUAL MEETING OF MILITARY SURGEONS IN WASHINGTON, D. C., NOVEMBER 12-14

The expanding horizons of military medicine will be the theme of the 63d annual convention of the Association of Military Surgeons of the United States which will be held at the Statler Hotel, Washington, D. C., from 12-14 November 1956. In addition to the program listed below, a record number of 14 technical and scientific exhibits have been planned for display throughout the meeting.

Monday Morning, 12 November

Presiding: Rear Adm. Winfred P. Dana, MC, USN, President

Association President's Address—Rear Adm. Winfred P. Dana, MC, USN, Assistant Chief for Aviation and Operational Medicine and Research and Medical Military Specialties, Bureau of Medicine and Surgery, Department of the Navy.

Welcoming Remarks—Edward H. Cushing, M. D., Deputy Assistant Secretary of Defense (Health and Medical).

Guest Speaker—Detlev W. Bronk, Ph. D., President, National Academy of Sciences.

Expanding Horizons: Career Incentives—Rear Adm. Bruce E. Bradley, MC, USN, Acting Surgeon General, Department of the Navy.

Medicare Law—Maj. Gen. Silas B. Hays, MC, USA, Surgeon General, Department of the Army.

Expanding Horizons of Aviation Medicine—Maj. Gen. Dan C. Ogle, USAF (MC), Surgeon General, Department of the Air Force.

Expanding Horizons: Teamwork in Civilian and Military Health Services—Leroy E. Burney, M. D., Surgeon General, U. S. Public Health Service, Department of Health, Education, and Welfare.

Expanding Horizons in Research and Education in the Veterans Administration—Roy A. Wolford, M. D., Deputy Chief Medical Director, Veterans Administration.

Monday Afternoon

Presiding: Winchell McK. Craig, Rear Adm., MC, USNR (Ret.), Section of Neurological Surgery, Mayo Clinic, Rochester, Minn.

Hormone-Producing Tumors—Roy Hertz, M. D., Chief, Endocrinology Branch, National Cancer Institute, National Institutes of Health.

Replacement Arthroplasty in Military Patients—Lt. Col. Earl W. Brannon, USAF (MC), 3700th U. S. Air Force Hospital, Lackland Air Force Base.

Preliminary Studies on Bovine Embryo Skin Grafts—Lt. A. N. Silvetti, MC, USNR, Naval Medical Research Institute, National Naval Medical Center, and Blair O. Rogers, M. D., Clinical Instructor in Plastic Surgery, New York University College of Medicine.

Experiences with the Adenovirus Vaccines in Navy Recruits (Co-operative studies of the U. S. Navy, the University of Chicago, and the U. S. Public Health Service)—Joseph A. Bell, M. D., Chief, Epidemiology Section, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health.

Tuesday Morning, 13 November

Presiding: Brig. Gen. Stanhope Bayne-Jones, MC, USAR (Ret.), Formerly Technical Director of Research, Office of the Surgeon General, Department of the Army.

Significance of Leptospirosis in Military Medicine—Lt. Col. Leslie C. Murphy, VC, USA, Deputy Director, Division of Veterinary Medicine, Walter Reed Army Institute of Research.

Rapid Extracorporeal Oxygenation of Banked Blood—Capt. William G. Malette, USAF (MC), Resident Surgeon, Denver Veterans Administration Hospital; William B. Summers, M. D., Denver Veterans Administration Hospital; and Ben Eiseman, M. D., Chief of Surgical Service, Denver Veterans Administration Hospital, and Associate Professor of Surgery, University of Colorado School of Medicine.

Military Operations in Radiologically Contaminated Areas—Lt. Col. James B. Hartgering, MC, USA, Director, Division of Physiology and Pharmacology, Walter Reed Army Institute of Research.

Anorganic Bone: Chemistry, Anatomy and Biological Reaction—Comdr. Fred L. Losee, DC, USN, Naval Medical Research Institute, National Naval Medical Center, and Lloyd A. Hurley, M. D., Harlan Memorial Hospital, Harlan, Ky.

Late X-Ray Evidence of Spontaneous Reduction of Dislocation of Cervical Intervertebral Discs—Benjamin H. Kesert, Col., USAR, Consultant in Neurology, Veterans Administration Hospital, Hines, Ill.; Associate, Department of Neurology and Psychiatry, Northwestern University Medical School.

X-Ray Cineradiography and Portable X-Ray Units—Adolph T. Krebs, M. D., Head, Radiobiology Department, Army Medical Research Laboratory, Fort Knox, Ky.

Tuesday Afternoon

Presiding: Col. Victor A. Byrnes, USAF (MC), Director of Professional Services, Office of the Surgeon General, Department of the Air Force.

Preservation of Whole Blood by Freezing—Harold F. Meryman, M. D., Department of Internal Medicine, Yale Medical School.

Cold Weather Survival—Maj. Stanley Lutz, Jr., USAF (MC), Assistant Surgeon, Headquarters, 18th Air Force, Donaldson Air Force Base.

Atherosclerosis and Lipid Metabolism—Daniel Steinberg, M. D., Chief, Section on Metabolism, National Heart Institute, National Institutes of Health.

Results of Early Studies on Effects of Sleep Deprivation—David McK. Rioch, M. D., Director, Division of Neuropsychiatry, Walter Reed Army Institute of Research.

A Hearing Evaluation of an Air Force Squadron of Jet Aircraft Maintenance Personnel—Capt. R. G. Hansen, USAF (MSC), Wright Air Development Center, Wright-Patterson Air Force Base.

Wednesday Morning, 14 November

Presiding: William S. Middleton, M. D., Chief Medical Director, Veterans Administration.

Neurological Complications of Spinal Anesthesia—Myron J. Levin, M. D., Clinical Professor of Anesthesia, University of Illinois College of Medicine, Chicago, Ill.; Assistant Chief, Anesthesia Section, Veterans Administration Hospital, Hines, Ill.

Radiation Control Problems Aboard Nuclear Submarines—Lt. Comdr. John H. Ebersole, MC, USN, Medical Officer, U. S. S. *Seawolf* (SSN 575).

Clotting Factor Abnormalities in Chronic Liver Disease—Joseph R. Goodman, Ph. D., Head, Physiological Research Unit, Medical Research Program, Veterans Administration Hospital, Long Beach, Calif.; Research Associate, Department of Biochemistry and Nutrition, University of Southern California Medical School, Los Angeles, Calif.

The Wholesomeness of Irradiated Food and Its Military Implications—Col. Tyron E. Huber, MC, USA, Research and Development Division, Office of the Surgeon General, Department of the Army.

Practical Application of Pulmonary Physiology for Small Hospitals—Maj. Robert B. Stonehill, USAF (MC), Chief of Pulmonary Disease Section, Lackland Air Force Hospital.

Wednesday Afternoon

Presiding: David E. Price, M. D., Assistant Surgeon General, U. S. Public Health Service, Department of Health, Education, and Welfare.

Future Trends in Military Aviation Medicine—Capt. Ashton Graybiel, MC, USN, Director of Research, School of Aviation Medicine, Naval Air Station, Pensacola, Fla.

Experiences in Evacuation of Severely Burned Patients—Lt. Col. Robert D. Pillsbury, MC, USA, Deputy Commander, Surgical Research Unit, Brooke Army Medical Center.

The Effect of Thyroid Ablation Upon Serum Cholesterol and β -Lipoprotein Spectrum—Joseph R. Goodman, Ph. D., Head, Physiological Research Unit, Investigative Medicine Service, Veterans Administration Hospital, Long Beach, Calif.; Research Associate in Biochemistry, University of California Medical School, Los Angeles, Calif.

Nurse Anesthetist Refresher Course—Capt. Richard J. Ward, USAF (MC), 7100th U. S. Air Force Hospital, Wiesbaden, Germany.

Medical Education for National Defense—Col. Shelden S. Brownston, USAF (MC), Director of Staff, Office of Secretary of Defense (Health and Medical).

The Tranquilizing Drugs—Edward V. Evarts, M. D., Acting Chief, Laboratory of Clinical Sciences, National Institute of Mental Health, National Institutes of Health.

Effects of Microwaves: Current and Proposed Research—Maj. Daniel B. Williams, USAF (MC), School of Aviation Medicine, U. S. Air Force, Randolph Air Force Base.

BLAKISTON'S NEW GOULD MEDICAL DICTIONARY, A modern comprehensive dictionary of the terms used in all branches of medicine and allied sciences, including medical physics and chemistry, dentistry, pharmacy, nursing, veterinary medicine, zoology and botany, as well as medicolegal terms, edited by *Normand L. Hoerr, M. D.*, and *Arthur Osol, Ph. D.*, with the cooperation of an editorial board and 88 contributors. 2d edition. 1,463 pages; 252 illustrations on 43 plates, 129 in color. The Blakiston Division, McGraw-Hill Book Co., Inc., New York, N. Y., 1956. Price \$11.50.

Here is the dictionary that medical writers and editors have been waiting for. Compiled by a distinguished editorial board and 88 eminent and authoritative contributors in specialized fields, this completely revised and enlarged new edition has kept pace with our ever-growing, rapidly changing, current medical and surgical language. Thousands of new entries (some 12,000), changes (8,000), and modernization of spellings and usage are incorporated; and obsolete and unused terms *have been deleted. Recognition of usage was a determining factor in selection.* With the exception of the tables on diet and veterinary doses, the same helpful tables and lists, some revised, comprise the appendix; the color plates and halftone illustrations remain as in the first edition. A new table on radioactive and other isotopes commonly used in medicine has been added.

Definitions are concise, clear, accurate. Pronunciation is simplified by syllable division and accent and, when necessary, by phonetic respelling. A convenient key to the respellings acts as a helpful, easy guide.

Rapid finding of any term is facilitated by clear italic, roman, and boldface type. When series of subentries follow main entries they have been set in indented columnar form and each item set off in boldface type.

Altogether, the practitioner, student, medical author and editor, and all others concerned with medicine and the allied fields will appreciate this practical, helpful, and discriminating work.—E. W. MARTIN

CLINICAL LABORATORY DIAGNOSIS, by *Samuel A. Levinson, M. S., M. D., Ph. D.*, and *Robert P. MacFate, Ch. E., M. S., Ph. D.* 5th edition. 1,246 pages; 244 illustrations and 13 plates, 11 in color. Lea & Febiger, Philadelphia, Pa., 1956. Price \$12.50.

Five years have elapsed since the last edition of this standard and highly regarded text in clinical pathology. It has been revised, enlarged by 100 pages, and brought up to date. However, the number and titles of the chapters are identical with the previous edition.

The entire chapter on hematology has been revised to include current knowledge of hemorrhagic diseases, anemias, and leukemias. Newer knowledge concerning hemoglobin components along with the use of paper electrophoresis in the analysis of these components is presented. The entire section on hematology is particularly well done. The section on chemistry includes new microchemical methods, additional spectrophotometric analyses, and the spectrum analysis of hemoglobin derivatives, as well as a new discussion on electrolyte balance studies. There is an adequate discussion of blood groups, Rh factor, and the Coombs' test, but the section on blood bank procedures is very brief for this extremely important phase of laboratory work. The reader is referred to the standard texts and reference manuals for details of these procedures. The methods for the performance of the Venereal Disease Research Laboratory slide and tube flocculation tests are included in the chapter on immunology and serology. There is even a brief discussion of the *Treponema pallidum* immobilization test. The chapter on bacteriology has been rewritten with the addition of the method for the determination of the antistreptolysin titer of sera and other new techniques. Modifications and improvements have been made in the chapters on tropical diseases and histologic technic. The section on legal medicine and toxicology is an excellent review or introduction to this special field. There is an adequate index as well as a table referring the reader to the proper page for important laboratory tests in the common diseases.

The authors have attempted to bring together in a single volume all the many phases of clinical pathology. They have achieved this objective in discussing the most useful methods of laboratory medicine in a systematic, concise manner. The book is well printed with numerous excellent illustrations. It is highly recommended to the medical student, medical technologist, practicing physician, and pathologist as an authoritative text in clinical laboratory methods.

—MILWARD W. BAYLISS, Col., MC, USA

DISEASES OF THE SKIN, by Richard L. Sutton, Jr., A. M., M. D., F. R. S. (Edin.). 11th edition. 1,479 pages; 1,972 illustrations. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$29.50.

The 11th edition of this standard textbook of dermatology is a worthy successor to the previous editions. During the 13 years since this book was last reprinted and emended, many advances have been made in the specialty, and the author has successfully noted and included in this work these additions. The author has been peculiarly successful in adding to the book hundreds of photographs, many more pertinent subjects and improved discussions. This edition is written more as an outline than previous ones, some subjects having been cut considerably, yet have been treated more precisely and informatively than before. The photographs are superb. The author has added the more recent therapeutic advances in pertinent portions of his text. ACTH, cortisone, and hydrocortisone are discussed, and their uses outlined. There

The author has been peculiarly successful in adding to the book hundreds of photographs, many more pertinent subjects and improved discussions. This edition is written more as an outline than previous ones, some subjects having been cut considerably, yet have been treated more precisely and informatively than before. The photographs are superb. The author has added the more recent therapeutic advances in pertinent portions of his text. ACTH, cortisone, and hydrocortisone are discussed, and their uses outlined. There

diagnostic, and therapeutic aspects of diseases of the skin. It is a brief, practical, and useful text for the student and practitioner.

The book is well illustrated with both black and white and colored plates, and the printing is excellent. Organization of the subject matter is practical and useful. Particularly helpful to the nonspecialist is the section included in each chapter on those aspects of nursing that are particularly germane to the diseases considered.

The chapter on general therapeutic suggestions will prove to be a most helpful guide to the beginner.

Dr. Tobias again has succeeded in presenting a wide and difficult subject in a concise and readable form, yet complete enough for everyday use. This book is highly recommended for students of medicine and the nonspecialist.—VICTOR R. HIRSCHMANN, Col., MC, USA

WORLD-ATLAS OF EPIDEMIC DISEASES, Part II, Fourth Issue, edited under the Sponsorship of the Heidelberger Akademie der Wissenschaften by Professor Dr. med. Ernst Rodenwaldt, Heidelberg, in Collaboration with Privatdozent Dr. med. habil. Helmut J. Juszatz, Heidelberg. 36 pages; 11 colored maps. Falk-Verlag, Hamburg 1, Germany, 1956. Price 32 Deutsche marks, plus extra charge for postage and packing.

Any attempt, such as this book makes, to portray African diseases in their entirety in so many diversely governed, seminomadic peoples living under such a variety of climatic and social conditions is bound to leave the student with a feeling of uncertainty. However, such comprehensive coverage will certainly serve as a very fine basis for future studies and evaluation of reports from these areas. Plague, leprosy, poliomyelitis, and smallpox are discussed in detail, and the great gaps in information are clearly stated in the text. The maps, as usual with this series, are detailed and contain data oriented as to time and place, but not as clearly as to race. The text clarifies the map presentations, but careful interpretation is required.

In discussing plague, it was noted that the gigantic wave between 1920 and 1930 carried the series of yearly and seasonal waves to a high crest. No explanation for this large wave was attempted, but it may help explain many baffling facts about plague in this and other areas.

Leprosy and its relationship to tuberculosis, diet, poor sanitation, migration, climate, living conditions, and customs are discussed, but no over-all panaceas are proposed. The changing picture of leprosy in Africa since 1900 and the conclusion, attributed to many authorities, that the total incidence is declining may be misleading. This problem is apparently still very great.

There are five fine climatologic maps of Africa that give fairly detailed data on January and July temperatures, total yearly precipitation in the rainy and dry seasons, and a map of thermal sultriness values (range of comfort)—all of which are of great value in considering the ecology of disease.—GOTTLIEB L. ORTH, Col., MC, USA

A TEXTBOOK OF OPERATIVE DENTISTRY, by William H. O. McGehee, D. D. S., M. D., F. A. C. D., Harry A. True, D. D. S., F. A. C. D., and E. Frank Inskip, D. D. S., F. A. C. D. 4th edition. 720 pages; illustrated. The Blakiston Division, McGraw-Hill Book Co., Inc., New York, N. Y., 1956. Price \$14.

This is the latest edition of a text that has been standard in its field since 1930. It presents the subject as completely as can be expected in one volume. The first two editions were authored by Doctor McGehee alone, he was joined by the named co-authors for the third edition, and the present edition lists 20 other contributors.

This is a thoroughly modern textbook. Narrative and outline forms of presentation are admirably blended to permit the inclusion of much material without increasing the difficulty of productive study. The 423 figures contain many hundreds of individual illustrations, plus figures from earlier editions. The use of new high-speed materials and technics is presented in a chapter entitled "Accuracy with Speed." In addition to the expected chapters dealing with dental caries, cavity form, cavity preparation, instrumentation, and filling materials, there are chapters discussing such subjects as efficiency in the arrangement of the dental office and the role of the dental assistant in operative dentistry. Endodontics is presented in a separate chapter, and there is a 93-page chapter on operative dentistry for children, authored by Charles A. Sweet, Sr., and I. Irwin Beechen. As in earlier editions, the importance of adequate diagnosis as a requisite to adequate restorative dentistry is stressed.

The material is both well organized and comprehensively treated; subjects are readily discoverable in the index, easily located in the text, and clearly and concisely presented. This volume can be recommended to both students and practicing dentists.

—JAMES E. CHIPPS, Lt. Col., DC, USA

NEW AND NONOFFICIAL REMEDIES 1956, Containing Descriptions of Drugs Evaluated by the Council on Pharmacy and Chemistry of the American Medical Association. An Annual Publication Issued Under the Direction and Supervision of the Council. 540 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$3.35.

This annual publication of the Council on Pharmacy and Chemistry of the American Medical Association describes drugs, arranged according to their pharmacologic action or clinical use, that have been evaluated by the Council but have not been included in the *Pharmacopeia of the United States*, *The National Formulary*, or, for a prior cumulative 20-year period, in previous *New and Nonofficial Remedies* (NNR). The scope of the book was expanded this year to include not only established useful drugs but also information on all available new drugs. As a result 60 monographs on new drugs were added this year, while only seven from last year's NNR were omitted.

Drugs are described under nonproprietary titles with their chemical or biologic identity, including their actions, uses, side effects, etc.

city, dosage, and routes of administration. Names of commercial preparations are listed after each monograph.

The general index at the end of the book lists the drugs by their commercial as well as their nonproprietary names.

This volume serves the purpose for which published: to give pertinent and reliable information on new and nonofficial remedies and thereby to encourage rational therapy.—PATRICK I. McSHANE, Col., MC, USA

TEXTBOOK OF MEDICAL PHYSIOLOGY, by Arthur C. Guyton, M. D. 1,030 pages; illustrated, W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$13.50.

This textbook is written primarily for students and is not a reference work. The author's stated intent is to present the philosophy and logic of the mass of knowledge needed by the physiologist and physician. He has accomplished this goal for the medical student by blending enough anatomy and pathology to stimulate the student's interest in the practical aspects of physiology. However, for the physiology student there is too little emphasis on basic mechanisms and the underlying biophysical principles involved. There is only an occasional use of mathematical models, which in many cases can cleverly and simply define a complicated process.

The book consists of 11 major subdivisions and 75 chapters. The subdivisions follow classical lines, *i. e.*, respiration, neurophysiology, circulation, et cetera. The physiologic aspects of aviation, deep-sea diving, and nuclear radiation are covered in special sections but are very brief. There are several misstatements in a short discussion of the "effects of the atom bomb blast on the body."

At the end of each topic a carefully selected bibliography is included. These references were selected for their own broad bibliographies as well as for their individual value and are exceedingly helpful.

In spite of the above limitations, this is a very readable book which will provide anyone interested in human biology with a readily understandable general review.—JAMES B. HARTGERING, Lt. Col., MC, USA

YEAR BOOK OF DERMATOLOGY AND SYPHILOLOGY (1955-1956 Series), by Rudolf L. Baer, M. D., and Victor H. Witten, M. D. 480 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1956. Price \$6.50.

This yearbook contains nearly 400 abstracts of articles received by the editors from December 1954 through November 1955. It has the same format and table of contents as previous editions and has an original article by the authors on therapy with superficial x-rays and Grenz rays. Many foreign articles are abstracted. Some abstracts are rather long and could be shortened to make room for summaries of additional articles. The editors emphasize the current studies on cutaneous enzymes and lipid metabolism, and new information is presented on the relationship of skin diseases and systemic involvement.

Acanthosis nigricans, *incontinentia pigmenti*, and *acrodermatitis atrophicans* are currently receiving much attention. *Psoriasis*, the ubiquitous enigma, is at long last receiving much therapeutic and biochemical investigation.

The abstracts on therapy are useful. Of interest are those on the use of ACTH, cortisone, and hydrocortisone. Various forms of radiation therapy for dermatoses are presented. The forms of radiation such as high-energy electrons and soft radiation from beryllium window tubes may prove of particular value, being highly effective on skin lesions and having little effect on the underlying tissues.

Dermatology needs a good cumulative index. Until one is produced, however, the yearbooks will provide a good working basis for the researcher as well as a general review source.

—WILLIAM N. NEW, *Capt., MC, USN*

OF WATER, SALT AND LIFE, an atlas of 36 pages illustrating 31 color plates, prepared and distributed by Lakeside Laboratories, Inc., Milwaukee, Wis., 1956.

This little book is a beautifully illustrated atlas of fluid and electrolyte balance in health and disease. It consists of 31 colored plates opposite short descriptions of such topics as acid-base balance, pharmacology of diuresis, congestive heart failure, cirrhosis, nephrosis, et cetera. Although some figures require a certain amount of concentration the book does present the feeling of dynamic processes. It should prove to be a valuable aid both to students and to practitioners who may deal with "water, salt, and life."—S. O. WAIFE, *Lt. Comdr., MC, USNR*

DISEASES OF THE ENDOCRINE GLANDS, by Louis J. Soffer, M. D., with J. Lester Gabrielove, M. D., and the Section on Gonads by Arthur R. Sobval, M. D. 2d edition. 1,032 pages; 102 illustrations and 3 plates in color; 28 tables. Lea & Febiger, Philadelphia, Pa., 1956. Price \$16.50.

The author discusses the diseases of endocrine glands in separate sections for each gland or, in a few cases, two glands. Reviews of anatomy, embryology, and physiology, which precede the clinical descriptions in each section, contain the details essential for complete understanding of clinically recognizable disease. The chapter on carbohydrate metabolism and diabetes mellitus, included in the first edition, has been excluded from this edition.

Many case reports are advantageously used to amplify the author's descriptions of diseases. The illustrations are clear and adequate, except for a paucity of pictures of patients. Greater use of structural chemical formulas and of tables to bring out similarities of, and differences between, various products of one endocrine gland could add to the value of future editions.

The clarity of presentation makes for easy reading and understanding. The author has, indeed, struck an excellent balance between space allotted to theory and to practice. The endocrinologist interested in the

historical development of our knowledge is unlikely to turn to this book, which is, however, excellently suited to the needs of other physicians.

Because the book is truly up to date in most respects, it was disappointing to read only of the intramuscular corticotropin-eosinophil test for adrenal cortical insufficiency in the section on Addison's disease. Reference is made to Thorn's work, published in 1948. In the appendix, tests using intravenous and intramuscular injection of ACTH are described. However, even there the limitations of the intramuscular injection technic are not discussed.

The appendix (which is devoted to laboratory tests of endocrine function) should be useful to most readers. It could be improved by clarifying the arrangement of order of the tests, perhaps by the use of a preliminary outline or by the use of headings.

In summary, this book can be recommended to general practitioners, internists, and specialists other than endocrinologists as a volume which combines discussions of physiology and disease, theory and practice, and clinical and laboratory aspects in optimum proportions.

—ROBERT J. HOAGLAND, Col., MC, USA

ADVANCES IN VETERINARY SCIENCE, Volume II, edited by C. A. Brandy and E. L. Jungherr, 449 pages; illustrated. Academic Press, Inc., Publishers, New York, N. Y., 1955. Price \$10.

This volume continues the approach made in 1953 in Volume I directed toward the periodic review of progress in the more active fields of research pertinent to veterinary medical science. The editors have had the benefit of a distinguished advisory board in the review and editing of the 11 individual contributions comprising the volume.

The subjects discussed are epizootiology of virus diseases, mycoses in animals, respiratory diseases of poultry, the blood groups of animals, disease caused by deficiencies of trace elements, photosensitization in animals, rumen dysfunction, bovine ketosis, tickborne rickettsioses in South Africa, vibriosis, and effective control of internal parasites.

Each subject is followed by a bibliography. The value of this work is further enhanced by complete author and subject indexes at the back of the volume.

The reviewer inevitably finds himself more interested in some of the areas concerned than in others. Likewise, the differences in approach by the several contributors are pronounced. These range from almost pedantic undergraduate-level abstracts of the literature to extraordinarily thought-provoking interpretations and estimations of the significance of the newly uncovered findings of veterinary and medical research.

The reviewer has seldom encountered a more fascinating and stimulating paper than the contributions on the epizootiology of virus diseases by R. E. Shope. This alone is sufficient to merit the inclusion

of the volume in the libraries of all interested in infectious disease and in veterinary medicine.

In like manner, the discussion of the blood groups of animals by L. C. Ferguson not only merits careful reading but further serves as a ready reference for valuable technics and methodology.

The editors, the advisory board, and the individual contributors have admirably met their objective of producing a volume "of greatest use to the serious student, the research worker, and the practitioner (of veterinary medicine)." This volume should be required reading for all veterinarians of the armed services.

—WILLIAM S. GOCHENOUR, Jr., Lt. Col., VC, USA

CAUSAL FACTORS IN CANCER OF THE LUNG, by Carl V. Weller, M. S., M. D. American Lecture Series, Publication No. 277, A Monograph in American Lectures in Chest Diseases, edited by J. Arthur Myers, M. D., Ph. D. 113 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$3.

Regardless of the time available, it is the dream of every lecturer to be permitted an additional 15 minutes to devote to his subject. The Charles C Thomas Company has done just this in a number of monographs called the "American Lecture Series." Outstanding authorities have been allowed to revise, expand, and annotate their most popular lectures. These have been published and, despite the variety of subjects and of authors, have generally maintained a very high quality. Strangely, the publishers "do not have a completely up-to-date list of The American Lecture Series." To the reviewer this seems a pity. Those volumes of the series which he has examined in the past have been worth owning.

The present volume is typical of this series. The lecture has been expanded to a monograph, supplemented by 121 carefully and well-chosen references. Following a discussion of general considerations, Dr. Weller develops in detail a first theme describing bronchogenic carcinoma as an endemic occupational disease in miners, a second theme describing the search for causes of cancer of the lung in the 20th century, and a third theme concerned with the relation between tobacco smoking and bronchogenic carcinoma.

Although the subject of the lecture is sharply limited, the material is presented in an interesting and even exciting manner. The author has accomplished his objective, which was to explore the "causes, intrinsic and extrinsic, proved and suspected, of bronchogenic cancer." The type and engravings are of high quality, the binding is leatherette, and the volume is handsome in appearance. It is recommended as a valuable addition in any general library and to physicians and workers with a special interest in this field. For those who may have to lecture on this subject, this monograph would be of considerable value.

—ARTHUR STEER, Lt. Col., MC, USA

CURRENT THERAPY, 1956, Latest Approved Methods of Treatment for the Practicing Physician, edited by *Howard F. Conn, M. D.*, and 12 consulting editors. 632 pages. W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$11.

This is the eighth edition of this compendium of therapy which fortunately has resisted the expansion in bulk which usually occurs with medical books from edition to edition. The contributors are selected from recognized authorities who are especially interested in the specific disease discussed. They vary with the edition and consequently new viewpoints are given. The outlines of therapy are brief and practical, and treatment methods found useful in the past are not discarded if still effective, although obsolete methods of treatment are omitted.

There is a multitude of new drugs available and those well tried are included; experimental drugs are not included, and note is made when treatment methods not fully tested are given.

At times two different methods of approaching treatment are noted, either of which might be followed successfully or from which the reader might evolve a third of his own, proving that medicine as an art is not yet dead.

This book is a useful desk reference, brief and to the point, which gives the essentials of therapy of each disease and the most up-to-date methods and drugs, and which prevents one's missing some new aspect of treatment.—*JAMES L. TOBIN, Col., USAF (MC)*

THERAPEUTIC USE OF ARTIFICIAL RADIOISOTOPES, edited by *Paul F. Hahn, Ph. D.* 414 pages; illustrated. John Wiley & Sons, Inc., New York, N. Y., 1956. Price \$10.

This 400-page volume represents a compilation of 29 research men's experience in the use of isotopes over a 20-year period. The editor's choice of authors seems for the most part to reflect his philosophy of being more forthright and willing to take some scientific risks in incurable patients in order to more fully understand the capabilities of these medical tools. He feels irradiation is a therapeutic weapon and is not the panacea to the cancer problem. He proceeds to show the results of thorough scientific research in an inspiring and challenging way.

The order of presentation of chapters is excellent. Prefacing the individual uses of isotopes is a section including a short history of the use of radioisotopes, the problems facing even the most astute scientist in using them, their procurement and safe handling, and their effects on tissue. Within these first chapters is an effective blending of doctors of medicine and doctors of other scientific fields. Chapters 2 and 3 might be disconcerting to the novice in this field, and possibly keep him from finishing the book. Yet the subjects of radiologic physics and dosimetry of internal radioisotopes are concisely presented, and by carefully studying these chapters a wide knowledge can be gained in a short time. The procurement of isotopes has been brought

up to date with the addendum to chapter 4. The work by Hymer L. Friedell and P. R. Salerno as reviewed in chapter 6 presents a challenge to all those working in this broad field. Radiation effect is little enough understood, let alone the effect of multiple types of radiation. These men outline methods of research into the synergistic effect of isotopes used in combination that would be well used by others in studying this most urgent problem. Edwin E. Osgood's chapter on the treatment of leukemias and polycythemia vera with radioactive phosphorus is a splendid review of a method of treating the complete patient. The basic histophysiology upon which this treatment is based has been well investigated by the author, and the complete way in which he outlines his course of therapy is excellent. The work by Osgood, Tivey Seaman, et al. is classical. The next chapter also deals with investigative methods for treatment of chronic leukemias, presenting case histories to highlight questions as to mode of action of radiation, problems faced during treatment, and choice of isotopes in treating this disease state.

Chapter 9 is an excellent review of the use of radioiodine in thyrotoxicosis and a brief note on its use in cardiac disease. Chapter 10, on treatment of thyroid carcinoma, is on clinical selection of patients, methods of use of iodine, dosimetry of radiation within the body, complications, a summary of what the author thinks is reasonable management of treatment, and safeguards for the patients and personnel.

The next seven chapters deal with specific colloids, applicators, and implants of isotopes within or on the body in attempts to ablate or palliate cancerous tumors. These chapters have been written by specialists in each field and represent the most advanced knowledge on these subjects. The last chapter, written by G. H. Fletcher, is a concise summary of this man's thought on the advantages and disadvantages of this method of treatment. The book is invaluable to specialist and general practitioner as a guide and review of what has been done in this field.—*RICHARD E. OGBORN, Maj., MC, USA*

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. Surgery in World War II. Hand Surgery, edited by Sterling Bunnell, M. D. 447 pages; illustrated. Prepared in the Historical Unit, Army Medical Service, under the direction of Colonel Calvin H. Goddard, MC, AUS. Editor-in-Chief, Colonel John Boyd Coates, Jr., MC, USA; Associate Editor for Hand Surgery, Mary E. McDonald; Assistant Editor, Janie W. Williams. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$3.50.

This volume is both a historical document and a report of a clinically important collective experience in the management of the injured hand. Although the format of résumés of experiences in the individual theaters of operation and hand centers results in considerable repetition, the basic principles of hand surgery are so unanimously and emphatically emphasized that their importance cannot be missed.

The book is well illustrated with photographs, sketches, and photographic copies of roentgenograms which are usually well placed to conform with the text. Many of the illustrations, however, are so reduced in size that their value is lost—this is particularly true of the roentgenograms.

The influence of the editor, as one of the pioneers in the field of hand surgery and as Civilian Consultant for Hand Surgery to the Secretary of War, is felt throughout the book. Chapter 2—consisting of his conclusions based on his experiences as consultant—is a highly concentrated digest of the principles and details of management of the injured hand, but as such might better have been placed at the end so that he could have commented on some of the differences in approach or viewpoint of the various contributors.

Many important lessons can be learned from this book. It is apparent that hand surgery is an important part of any mass casualty situation and that proper care of the injured hand begins in the field. The need for specialized centers staffed by trained and interested personnel is stressed. This is particularly true in the reconstructive phase of hand surgery.

This book is an important contribution to the field of the surgery of trauma. Based on a wide experience, it is a source of general and specific information on all phases of the management of the injured hand. It should be an invaluable addition to the library of the military and industrial surgeon.—HASKELL M. WERTHEIMER, *Comdr., MC, USN*

EPITOME of the Pharmacopeia of the United States and the National Formulary with Comments. Issued under the Direction and Supervision of the Council on Pharmacy and Chemistry of the *American Medical Association*. 10th edition. 322 pages. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$3.

For the benefit of those not familiar with this volume, it is designed to follow the material published in the *Pharmacopeia of the United States* and the *National Formulary*, but to present it in such a form that it will be more valuable to physicians. The two volumes mentioned provide the standards for drugs and drug preparations; however, they also contain much detail that is of value to the pharmacist or drug manufacturer but is of little interest to physicians.

The present edition, of convenient size as to make its ready reference inviting, contains only the essential definitions and descriptions of the drugs listed, with more detail as to the nature of the remedies, their uses and doses. Adverse comment is made on preparations believed to be of doubtful value; however, the wisdom of this is questioned in view of the great deliberation which goes into the acceptance of drugs for the official volumes.

The items are arranged alphabetically by their English names, the uses of which are of particular interest to the prescribing physician,

as is the information relative to market preparations in which the drugs may be found.

Some of the words of caution found in the official volumes are omitted from this volume. This point is of little importance in those cases where the "caution" was directed at the manufacturer or the dispenser. However, in those cases where the words of caution were of prime importance to the physician prescribing the medicines, their omission could possibly have a disastrous effect.

The reference tables are a handy aid, and the organization is well planned. The volume should prove to be a valuable adjunct to the physician's desk or library.—ELWOOD M. WRIGHT, Col., MSC, USA

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. *Vascular Surgery in World War II*, edited by Daniel C. Elkin, M. D., and Michael E. DeBakey, M. D. 465 pages; illustrated. Prepared in the Historical Unit, Army Medical Service, under the direction of Colonel Calvin H. Goddard, MC, AUS. Editor-in-Chief, Colonel John Boyd Coates, Jr., MC, USA. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$4.25.

This volume of the medical history of World War II gives a detailed accounting of complications of traumatic vascular injuries in casualties evacuated to the zone of interior. In this book is statistically recorded what is probably the largest and certainly the most recent and most complete series of vascular injuries to date. Although primarily of historical and statistical nature, the authors have included diagnostic methods, various tests, surgical approaches and techniques as well as valuable pre- and post-operative physiologic data.

The authors tabulate the expected incidence of gangrene which may follow ligation of major vessels. In doing so, Makins' World War I figures on the subject are clarified as is misleading information in the 1943 Military Surgical Manual relative to the expected incidence of gangrene following ligation.

Care of the patient with traumatic aneurysms and arteriovenous fistulas is fully discussed. Additional space is allotted to the systemic effects of arteriovenous fistulas. Statistical data is presented on the results of obliterative operations for these lesions and the value of reparative surgical intervention is stressed. Along with the discussion on surgery is the consideration for sympathectomy. In addition to this excellent study of traumatic aneurysms and arteriovenous fistulas, the incidence, diagnosis, and treatment of patients in World War II with other peripheral vascular disturbances and vasospastic disorders are presented.

Although most of the material in this volume was published in various medical journals prior to this compilation, it is regrettable that this volume was not available for reference at the beginning of the Korean conflict. While this volume is regarded as particularly valuable for

those doing vascular surgery and especially those in the service during hostilities, it is extremely valuable for the use of all general surgeons who may have occasion to treat the complications of acute vascular injuries.—CARL W. HUGHES, Lt. Col., MC, USA

MIGRAINE AND PERIODIC HEADACHE, A Modern Approach to Successful Treatment, by Nevil Leyton, M. A. (Cantab.). 2d edition, reprinted. 122 pages. Published by William Heinemann Medical Books, Ltd., London, England, 1954. Distributed by Charles C Thomas, Publisher, Springfield, Ill. Price \$2.50.

This small, 122-page textbook on headache is as fascinating to the reader as a work of fiction. However, it encompasses the leading scientific theories on etiologic mechanisms of headache and includes some concepts new to this reviewer. Detailed points in the history and physical examination are listed on the differential diagnosis. In addition, a relatively simple method of tackling the migraine problem is presented. This is long-term treatment with the aim of preventing headaches, lengthening the interval between them, or ameliorating the attacks. In fact, the most commonly prescribed relief remedies are barely mentioned.

The author is certain that there are two factors present in the production of migraine: first, an organic diathesis which enables a second, sensitizing factor to produce the alteration of arterial calibre that causes the intracranial pain. A "trigger mechanism" is necessary to set off the sensitizing factor. This latter may be an overproduction of histamine, the cyclic swing of the estrogenic hormones, or the activation by weather, strain, or chronic disease of a neuralgic syndrome. The "trigger" may be psychologic upset, worry, or fatigue.

Treatment is individualistic and includes the progressive injections of an anterior-pituitary-like hormone, histamine injections, the oral use of prostigmine in progressive courses, and the parenteral administration of Vitamin B₁₂ as well as the use of several other less effective drugs.

Nineteen selective case histories are presented and discussed to illustrate various types of headaches and responses to therapy. Economic and social considerations are presented. The book has a summary of conclusions and a good bibliography, and is well indexed. Illustrations consist only of tables and schedules of treatment.

This book is highly recommended to all physicians who see and fret with many patients with headaches. It gives a positive approach toward treatment and an optimistic outlook for doctor and patient alike. I cannot evaluate or corroborate the results of treatment by these methods, as there has been only sufficient time since receiving this book to start a few patients on some of the therapies recommended. If others can give relief to 75 per cent of migraine patients as the author does, or even to a smaller percentage, this book will be a most useful reference in managing these recurring minor tragedies of everyday practice.

—HORACE C. GIBSON, Col., MC, USA

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. *Preventive Medicine in World War II, Volume II: Environmental Hygiene*. 404 pages; illustrated. Prepared in the Historical Unit, Army Medical Service. Editor-in-Chief, Colonel John Boyd Coates, Jr., MC. Editor for Preventive Medicine, Ebbe Curtis Hoff, Ph. D., M. D. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$3.50.

This volume is one of a series on preventive medicine in the U. S. Army during World War II and records those plans, operations, and activities which modified or controlled the environment for health purposes. The authors have selected from the mass of data available to them those events which highlight the general principles of environmental hygiene and their application under the varying conditions of global warfare. The areas of environmental hygiene covered in this review include: food management, housing, water purification, waste disposal, insect and rodent control, and foreign quarantine. In addition, this volume contains an excellent résumé of the major research developments in preventive medicine during the war, as well as a discussion of the many health problems encountered at the various ports of embarkation.

The result is a concise, well-organized treatise on environmental hygiene as it pertains to a military population during mobilization. It gives the reader a comprehension of the effort, planning, and staffing required of the Medical Department in the successful execution of its mission.

Highly recommended reading for all officers, medical or line, whose present or future responsibilities require a broad knowledge of the means by which military populations are maintained in a state of healthful equilibrium with their environment, it is also recommended for public health officers, graduate students of preventive medicine, civil defense officers, and anyone whose needs require an excellent reference of this type. —HARVEY G. TOUSIGNANT, Lt. Col., USAF (MC)

LAUGHTER AND THE SENSE OF HUMOR, by Edmund Bergler, M. D. 297 pages. Intercontinental Medical Book Corp., New York, N. Y., 1956, in cooperation with Grune & Stratton, Inc., New York, N. Y. Price \$5.

The essence of this entertaining psychoanalytic book is described in the foreword: "The present volume attempts to bring the analytic theory on laughter and wit up to date . . . This book proposes to show that laughter is a necessary and healthy *internal* debunking process and, therefore, a fear-reducing process . . ."

Liberal sprinkled with jokes, bright sayings, and witticisms, the book covers the many theories of humor, and the author presents his own interpretation clearly and forcibly. Although some familiarity with psychiatric concepts (superego, psychic masochism, et cetera) is helpful in appreciating the various points of view expressed, even the non-psychiatrist can find much of interest in this book.

—S. O. WAIFE, Lt. Comdr., MC, USNR

THORACIC SURGERY FOR PHYSIOTHERAPISTS, by Gladys M. Storey, B. R. N., F. C. S. P., with a foreword by N. R. Barrett, M. Chir., F. R. C. S. 132 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$3.

The author of this book provides valuable insights for the student and practicing physical therapist into the conditions which they will encounter and treat in their work. It is a book of basic principles rather than an extensive and detailed study. It offers an understanding of conditions in thoracic surgery which should promote the use of more efficient treatment procedures.

The scope of thoracic surgery has expanded in recent years and now includes the management of many conditions for which, formerly, nothing curative could be attempted. Information on these new technics and procedures will be found in this book. There is discussion of pulmonary, pleural, cardiac, vascular, pericardial, mediastinal, esophageal, and neurologic conditions.—AGNES P. SNYDER, Lt. Col., AMSC (PT)

TUMORS OF THE SKIN, by Herbert Conway, M. S., M. B., M. D., F. A. C. S. A Monograph in The Bannerstone Division of American Lectures in Surgery, edited by Michael E. DeBakey, M. D., and R. Glen Spurling, M. D. Plastic Surgery Division, edited by James Barrett Brown, M. D. 267 pages; 178 figures; 3 plates in color. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$13.50.

This monograph is divided into two major sections. The first concerns benign tumors of the skin and the second the malignant tumors of the skin.

Each type of tumor is briefly presented. The discussion is chiefly concerned with clinical characteristics and physical findings, frequency of occurrence, treatment, and follow-up data. Following the discussion of each of the various tumors there is a short bibliography with references as recent as 1954.

Surgical treatment of tumors of the skin is emphasized and there is no attempt made to discuss extensively radiation technics or other nonsurgical methods of treatment. The book is profusely illustrated with photographs of patients with tumors before and after therapy and with artists' sketches of particular operative technics. However, the book is not a textbook of surgery. The operative technics illustrated and discussed are to a large extent detailed to emphasize the application of surgical methods in the removal of skin tumors in locations formerly considered beyond the scope of surgical approach and assigned to nonsurgical methods of therapy.

The arrangement of material in this book and the printing makes it easy to read and to use as a ready reference text. The book should be a valuable addition to the library of interns, residents, and advanced surgeons and should also prove interesting to those in other specialties.

—GEORGE F. PEER, Col., MC, USA

New Books Received

Books received by the *U. S. Armed Forces Medical Journal* are acknowledged in this department. Those of greatest interest will be reviewed in a later issue.

- POLYSACCHARIDES IN BIOLOGY**, Transactions of the First Conference, April 27, 28, and 29, 1955, Princeton, N. J., edited by *Georg F. Springer*, M. D. 271 pages; illustrated. Josiah Macy, Jr. Foundation, New York, N. Y., 1956. Price \$5.
- PROPRIOCEPTIVE NEUROMUSCULAR FACILITATION**, Patterns and Techniques, by *Margaret Knott*, B. S., and *Dorothy E. Voss*, B. Ed. Illustrations by *Helen Drew*. Foreword by *Sedgwick Mead*, M. D. 135 pages; illustrated. Paul B. Hoeber, Inc., Medical Book Dept. of Harper & Bros., New York, N. Y., 1956. Price \$5.50.
- CLINICAL ORTHOPAEDICS**, No. 7, "Tumors of Bone." This number contains a special third section on "Motorist Injuries and Motorist Safety" by *Jacob Kulowski*, M. D. *Anthony F. DePalma*, Editor-in-Chief. 354 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$7.50.
- PROCTOLOGY**, by *Harry E. Bacon*, M. D., ScD., LL. D., F. R. S. M. (Lond.), F. A. C. S., F. I. C. S. (Hon.), F. P. C. S. (Hon.), F. J. C. S. (Hon.), F. B. C. S. (Hon.), *Stuart T. Ross*, M. D., F. A. C. S., F. A. P. S., F. I. C. S., and *Porfirio Mayo Recio*, M. D., M. Sc., F. P. C. S., F. I. C. S. 441 pages; 228 illustrations and 5 plates in full color. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$10.
- FUNDAMENTALS OF NURSING**, The Humanities and the Sciences in Nursing, by *Elinor V. Fuerst*, R. N., M. A., and *LuVerne Wolff*, R. N., M. A. 592 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$5.
- PRINCIPLES AND METHODS OF STERILIZATION**, by *John J. Perkins*, M. S. 340 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$8.
- ULCERS OF THE LEGS**, by *Pedro Piulachs*, M. D. 574 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$15.50.
- EMOTIONAL HAZARDS IN ANIMALS AND MAN**, by *Howard S. Liddell*, Ph. D. American Lecture Series, Publication Number 299, A Monograph in American Lectures in Objective Psychiatry, edited by *William Horsley Gantt*, M. D. 97 pages. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$2.50.
- ESSENTIAL UROLOGY**, by *Fletcher H. Colby*, M. D. 3d edition. 656 pages; illustrated. Williams & Wilkins Co., Baltimore, Md., 1956. Price \$8.
- DERMATOLOGY**, by *Donald M. Pillsbury*, M. A., D. Sc. (Hon.), M. D.; *Walter B. Shelley*, M. D., Ph. D.; and *Albert M. Kligman*, M. D., Ph. D. 1,330 pages; 1,117 illustrations on 564 figures. W. B. Saunders Co., Philadelphia, Pa., 1956. Price \$20.
- A GUIDE FOR PSYCHIATRIC AIDES**, by *Charlotte R. Rodeman*, R. N., B. S., M. Ed. 234 pages. The Macmillan Co., New York, N. Y., 1956.

- PRACTITIONERS' CONFERENCES**, Held at the New York Hospital-Cornell Medical Center. Volume 4, edited by *Claude E. Forkner*, M. D. 407 pages; illustrated. Appleton-Century-Crofts, Inc., New York, N. Y., 1956.
- ROENTGEN SIGNS IN CLINICAL DIAGNOSIS**, by *Isadore Meschan*, M. A., M. D., with the assistance of *R. M. F. Farrer-Meschan*, M. B., B. S. 1,058 pages; 2,216 illustrations on 780 figures. W. B. Saunders Co., Philadelphia, Pa., 1956.
- SURGERY FOR GENERAL PRACTICE**, by *Victor Richards*, M. D. 947 pages; 476 illustrations. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$17.50.
- HUMAN ANATOMY AND PHYSIOLOGY**, by *Nellie D. Millard*, R. N., M. A.; *Barry G. King*, Ph. D.; and *Mary Jane Showers*, R. N., M. S. 4th edition. 593 pages; 315 illustrations with 55 in color. W. B. Saunders Co., Philadelphia, Pa., 1956.
- J. A. M. A. CLINICAL ABSTRACTS OF DIAGNOSIS AND TREATMENT**, 1956, published with the Approval of the Board of Trustees, American Medical Association. 661 pages. Intercontinental Medical Book Corp. with Grune & Stratton, Inc., New York, N. Y., 1956. Price \$5.50.
- PSYCHOPATHY AND DELINQUENCY**, by *William McCord*, Ph. D., and *Joan McCord*, Ed. M. 230 pages. Grune & Stratton, Inc., New York, N. Y., 1956. Price \$6.50.
- STUDIES IN TOPECTONY**, edited by *Nolan D. C. Lewis*, M. D.; *Carney Landis*, Ph. D., D. Sc.; and *H. E. King*, Ph. D. 248 pages. Grune & Stratton, Inc., New York, N. Y., 1956. Price \$6.75.
- NEW BASES OF ELECTROCARDIOGRAPHY**, by *Demetrio Sodi-Pallares*, M. D., with the collaboration of *Royall M. Calder*, M. D. 727 pages; 520 illustrations. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$18.50.
- CLINICAL UROLOGY FOR GENERAL PRACTICE**, by *Justin J. Cordonnier*, M. D., F. A. C. S. 252 pages; illustrated. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$6.75.

Monthly Message

In the February 1, 1956 number of the *Canadian Medical Association Journal* there is a thoughtful editorial on "The Integration of Medical Research." I should like to quote its first paragraph:

Like Humpty Dumpty, medicine has undergone considerable fragmentation; many are in agreement that the time has come to attempt to put the pieces together again, but, as in the case of Humpty Dumpty, the task is proving extremely difficult. There is a steady movement still continuing towards increasing the subdivision of medical science into sub-specialties; there is also an increasingly strong movement towards a cross-fertilization of one discipline by others. It is as yet impossible to forecast the eventual outcome of these two processes but there is no doubting the grave concern which exists at the ignorance of so many sub-specialists regarding work in other fields.

Unfortunately the splintering of medicine into smaller and smaller subspecialties continues. This may be all very well but I should like to recall the well-known epigram that the expert or specialist is one who knows more and more about less and less. The true specialist is one who considers the patient as a whole in addition to whatever "special" pathological condition he has. Therefore the last sentence in the above paragraph is particularly worthy of consideration.

ETIOLOGIC ASPECTS OF ATHEROSCLEROSIS

HORACE C. GIBSON, *Colonel, MC, USA*

THERE is today a vast mass of theory, clinical experience, and investigative data dealing with atherosclerosis. There have been many opposing views, and data have been interpreted differently. I shall try to discuss briefly the more pertinent phases of the problem.

Atherosclerosis is civilized man's greatest killer. Although it has been demonstrated literally from the "cradle to the grave," it takes its greatest toll during middle age—broadly, in men from 40 to 60 years of age and in women from 50 to 70. There is no method of ante-mortem diagnosis before near-total or total closure of an artery, usually a coronary. The emphasis in research is on finding some reliable laboratory methods to tell us which individual is imminently prone to a major catastrophe resulting from the rapid development of atherosclerosis. This goal has not been reached, and, what is more disheartening, the development of successful treatment appears to be as slow and as fraught with pitfalls as methods of diagnosis. Advances, however, are being made in both diagnosis and treatment.

The fine work of Gofman and associates¹ on the mechanism of atherosclerosis, presented in 1950, was of such importance that the United States Public Health Service organized a controlled study of the problem. Page² describes how four laboratories—Berkeley (Gofman and Jones), Pittsburg (Laufer, Hanig, and Barach), Boston (Stare and Mann), and Cleveland (Lewis and Page)—were designated, and work started in the winter of 1950. More than a year was required before the centrifuge analyses and cholesterol measurements agreed sufficiently among these labor-

From U. S. Army Hospital, Fort Jackson, S. C.

Foreword

The *United States Armed Forces Medical Journal* is the medium for disseminating information of administrative and professional interest to all medical personnel of the Department of Defense. The Assistant Secretary of Defense (Health and Medical) and the Surgeons General of the several services invite all medical officers, dental officers, Medical Service Corps officers, Nurse Corps officers, and officers of the Veterinary Corps of the Armed Forces, and the medical consultants of the Army, Navy, and Air Force to submit manuscripts for publication in this *Journal*.

Assistant Secretary of Defense (Health and Medical).

MAJOR GENERAL SILAS B. HAYS,
Surgeon General, United States Army.

REAR ADMIRAL BARTHOLOMEW W. HOGAN,
Surgeon General, United States Navy.

MAJOR GENERAL DAN C. OGLE,
Surgeon General, United States Air Force.

Neither cholesterol nor the other lipids, phospholipid and neutral fat, exist in plasma as pure substances. Lipids are the only large class of vital substances insoluble in water. They are bound to protein in the form of complex lipoprotein molecules. These compounds of lipoproteins contain different proportions of cholesterol, phospholipid, triglycerides, and protein. Electrophoretic or chemical techniques separate them grossly into alpha and beta lipoproteins. Ultracentrifugal analysis results in a classification of high- and low-density lipoproteins of varying S_f .

The low-density lipoproteins are considered to be the beta lipoproteins of chemical analysis, and abnormally high values of these are found in clinical heart disease. The high-density, smaller lipoproteins are considered to be alpha lipoproteins, although the precise relationship has not been clarified.² Lipoproteins serve as important vehicles for lipids, certain vitamins, and probably hormones.³

The average laboratory can determine a total serum cholesterol. This is of significant help if done on a fasting specimen. Although this tells us nothing of the low-density or beta lipoprotein levels, there is fair correlation of high cholesterol levels in atherosclerosis, the usual cause of coronary heart disease. The more elaborate methods of study are extremely expensive. The electrically driven analytic ultracentrifuge which uses an optical and photographic system costs about \$18,000. The maintenance costs on it are very great, and its operation requires a full-time technical staff of two persons. Some attempts have been made to get more accurate results in the separation of the lipoproteins fractions by using the differential preparative machine for separating out the various density lipids, and then running phospholipid, cholesterol, and neutral fat determinations on each of these fractions as well as on the whole serum. There is a prodigious amount of work to be done experimentally before any possible short cuts can be developed. The machine in this case costs only \$5,000.⁴

The hyperlipemia of nephrosis as well as of some other diseases is dependent on a metabolic disorder which involves protein as well as lipid. Page suggests that a defect in the synthesis or degradation of the protein moiety of the lipoproteins might be at fault, and that this possible defective protein metabolism may be as important as defective lipid metabolism in atherogenesis.

"FILTRATION" THEORY

The arteries are respiring, pulsating musculofibrous tubes. The arterial tissue uses oxygen and nourishment and is supplied by vasa vasorum—numerous small arteries distributed to the outer fibrous and elastic layer (tunica externa) and to the tunica media, the muscular layer. The blood is returned by small venae vasorum from the same layers. The inner layer, or tunica intima,

atories. Next, the serum of 12,000 normal people was studied, and each year since a follow-up has been made to determine whether myocardial infarction or other evident vascular disease has developed. These data are now undergoing statistical treatment in Washington. The first results are expected to be published sometime this year.¹

In essence, Gofman's working hypothesis of lipoprotein inter-conversions is that a certain class of lipoproteins, *i. e.*, those with serum flotation (S_f) rates between 12 and 20 Svedberg units, are atherogenic. In humans, molecules in the S_f 12-20 class were found to contain about 30 per cent cholesterol and little protein. The quantitative presence of these molecules was statistically related to atherogenesis. Later a second class of molecules was added as significant in atherogenesis, namely, the S_f 20-100, and still later another class, S_f 100-400, less significant in atherogenesis and which may be greatly elevated by a fat meal. Lipid may enter this system in the form of high S_f lipoproteins, and as these complexes yield their neutral fat to the body depots, high S_f lipoproteins are successively changed to lower S_f members of the series.² Are these restricted classes of serum lipoproteins, when they are in high quantity in the circulating blood, the ones which signal developing atheroma? As yet there is no clear answer, but the trend among most authorities is toward accepting this concept. However, until the conclusions of the joint laboratory study are known, Gofman's concepts must be considered neither confirmed nor denied.

Goldbloom and associates³ recently reported on the study of 500 subjects aged 13 to 100 years and found that at the ages of 60 to 75 years the trend toward increase of total lipids, certain serum lipoproteins, the atherogenic index, and the incidence of aortic dilatation is reversed. All these values begin to decline due to some invisible, not-understood barrier. Normal persons thus acquire their "second youth," and this may explain why they attain such ages as 80 to 100 years. On the other hand, perhaps those who do had throughout life a favorable chemical balance of their androgen and estrogen production.

NATURE OF INVOLVED LIPIDS AND PROTEINS

Absorption of cholesterol from the intestinal tract is by lymphatics along with fats and the necessary bile. Cholesterol esterified with fatty acids constitutes about 70 per cent of plasma cholesterol and is the more stable form of cholesterol. The liver appears to be necessary for conversion of the free to the ester form. Most tissues, except brain, can synthesize cholesterol, but the liver is most active in this regard, and the evidence points to the control of the plasma cholesterol by the liver.²

Neither cholesterol nor the other lipids, phospholipid and neutral fat, exist in plasma as pure substances. Lipids are the only large class of vital substances insoluble in water. They are bound to protein in the form of complex lipoprotein molecules. These compounds of lipoproteins contain different proportions of cholesterol, phospholipid, triglycerides, and protein. Electrophoretic or chemical techniques separate them grossly into alpha and beta lipoproteins. Ultracentrifugal analysis results in a classification of high- and low-density lipoproteins of varying S_f .

The low-density lipoproteins are considered to be the beta lipoproteins of chemical analysis, and abnormally high values of these are found in clinical heart disease. The high-density, smaller lipoproteins are considered to be alpha lipoproteins, although the precise relationship has not been clarified.⁴ Lipoproteins serve as important vehicles for lipids, certain vitamins, and probably hormones.³

The average laboratory can determine a total serum cholesterol. This is of significant help if done on a fasting specimen. Although this tells us nothing of the low-density or beta lipoprotein levels, there is fair correlation of high cholesterol levels in atherosclerosis, the usual cause of coronary heart disease. The more elaborate methods of study are extremely expensive. The electrically driven analytic ultracentrifuge which uses an optical and photographic system costs about \$18,000. The maintenance costs on it are very great, and its operation requires a full-time technical staff of two persons. Some attempts have been made to get more accurate results in the separation of the lipoproteins fractions by using the differential preparative machine for separating out the various density lipids, and then running phospholipid, cholesterol, and neutral fat determinations on each of these fractions as well as on the whole serum. There is a prodigious amount of work to be done experimentally before any possible short cuts can be developed. The machine in this case costs only \$5,000.⁶

The hyperlipemia of nephrosis as well as of some other diseases is dependent on a metabolic disorder which involves protein as well as lipid. Page suggests that a defect in the synthesis or degradation of the protein moiety of the lipoproteins might be at fault, and that this possible defective protein metabolism may be as important as defective lipid metabolism in atherogenesis.

"FILTRATION" THEORY

The arteries are respiring, pulsating musculofibrous tubes. The arterial tissue uses oxygen and nourishment and is supplied by vasa vasorum—numerous small arteries distributed to the outer fibrous and elastic layer (tunica externa) and to the tunica media, the muscular layer. The blood is returned by small venae vasorum from the same layers. The inner layer, or tunica intima,

in arteries of medium size is composed of the endothelial lining, a thin layer of fine areolar tissue fibers and cells called sub-endothelial areolar tissue, and a layer of elastic fibrils running more or less longitudinally, forming an elastic, fenestrated membrane called the elastic lamina.

Apparently the intima has no capillaries running through it. Cleftlike intercellular spaces are present in the intima and media. They may be regarded as the commencement of lymph vessels, but definite lymph vessels are found only in the outer tunic.⁷ The "filtration" concept of atherogenesis subscribed to by Page⁸ and Martt and Connor⁹ and generally accepted is as follows: Lipoprotein molecules filter from the plasma by lateral arterial pressure through the intima and into the media where they are picked up by the capillaries or by the adventitial lymph ducts. Some of these lipoprotein particles get caught in the subendothelial areolar tissue, either because the vessel fails to function properly as a filter or because the size, shape, and charge of the lipoproteins is such as to allow them to stick.

There is clear evidence that subendothelial fibroblastic proliferation, defects in the inner elastic lamella, and changes in the ground substance often are quite as impressive and may even precede the lipid changes of atherosclerosis. Changes in the arrangement, amount, and chemical nature of subendothelial ground substance may alter the filter function. This layer becomes thicker with long stress of hypertension. The nature of the lipid deposited and the responsiveness of the tissue to it will determine whether the lesion remains quiescent or whether a tissue reaction occurs which may cause necrosis and/or initiate a mural thrombus.²

Histologists tell us that mural thrombi are common in arteries during middle age and later. Most are asymptomatic, are soon covered by endothelium, and incorporated into the intima, gradually fibrosing and becoming additional layers to the atherosclerotic plaques. Segmental arterial spasm around a fresh thrombus may cause complete closure in an otherwise partially open vessel, hence the very great importance of nitrites in the treatment of early coronary occlusion.²

In early atherosclerosis the vessel wall shows a slowly progressive increase in total lipid content, of similar composition to plasma. This continues for some time and supports the view that the source of the vessel wall lipid is plasma lipid. The beta lipoprotein is considered to be the chief carrier of unstably held lipid. As the filtered lipoprotein breaks down, this "lightly bound" lipid is shed within the vessel wall. This lipid, freed from its combination with protein, is now insoluble in water, is foreign,

and is the nidus of a foreign-body reaction. As necrosis occurs, the normal plasma constituents, neutral fat, phospholipid, and free cholesterol decrease, and ester cholesterol increases disproportionately.

The basis of this concept accepts the movement of large amounts of plasma constituents through the vessel walls. To review all the work supporting this theory is not within the scope of this article.

HYPERTENSION, OTHER ASSOCIATED DISEASES

When Master's criteria¹⁰ are used, 5 per cent of individuals may be expected to have hypertension. Recently Goldstein and associates¹¹ found that 23.7 per cent of 135 males and 55 per cent of 65 females with coronary occlusion had hypertension. Therefore, hypertension occurred 4.75 times more frequently in their group of males and 11.5 times more frequently in their group of females with coronary occlusion than in otherwise comparable individuals without coronary occlusion. Hypertension is relatively more important in the female. This can be explained on the increased susceptibility of males in the fifth and sixth decades to atherosclerosis with or without hypertension. Premenopausal women are less prone to develop atherosclerosis and coronary occlusion, with or without hypertension. This is presumed to be due to the protective high estrogen production. Castrated women do not manifest this protection.

The concentration of alpha and beta lipoproteins is normal in early essential hypertension. But, as it becomes severe or malignant, the classes of lipoproteins considered by Gofman and associates to be atherogenic all increase. The development of vascular disease, atherosclerotic, and/or hypertensive, especially if there is renal involvement, seems to be associated with great disturbance in the normal lipoprotein pattern of the blood.

Nephrotic, diabetic, and myxedematous patients also show abnormal lipoprotein patterns. These are examples of accelerated atherogenesis, and do not preclude other more slowly progressive varieties in which there is no detectable change in lipoproteins from what we consider normal.²

Idiopathic hyperlipemia is a hereditary condition in which there is a high fasting level of serum neutral fat. The triad of signs and symptoms includes abdominal pain, hepatosplenomegaly, and cutaneous xanthomata. Gofman and associates indicated that these patients have elevations of lipoprotein molecules of the classes S₁ 100-400 which are normally elevated after the ingestion of dietary fat. Clearance tests for orally ingested neutral fat, tagged with radioactive iodine, and vitamin A tolerance tests indicate a striking delay in the clearance of fat from the serum.

The condition is thought to be due to failure of liver and fat depots to remove dietary fat from the blood stream at a normal rate. The cause may, however, be an inherent inability to form adequate amounts of heparin. Restriction of dietary fat, with or without heparin, relieves the symptoms and lowers the plasma lipid much like restriction of carbohydrate, with or without insulin, lowers blood sugar and relieves the symptoms of diabetes mellitus. Hyperlipemic patients are subject to symptoms of coronary insufficiency which are relieved by treatment. Recently Mart and Connor⁴ reported the first autopsied case of coronary occlusion occurring in a patient with idiopathic hyperlipemia.

ENVIRONMENT

Factors of habit and environment as well as inheritance have been blamed as causes of atherosclerosis. I shall dismiss tobacco and alcohol from further discussion as there is insufficient reliable evidence on which to incriminate them in causing atherosclerosis. There is good evidence that tobacco increases established coronary insufficiency, probably by spasm—hence its importance here. And, at the risk of being very unpopular, I must say that reliable work does not bear out the coronary dilating theory of alcohol.⁴ Perhaps we can still be comforted by the thought that, used properly, alcohol relieves some of the anxiety and stress of the day and under its mellowing influence we can have our coronary occlusions with less pain and strain.

Exertion within limits is more beneficial than harmful. The active man metabolizes exogenous dietary cholesterol and fats faster than the sedentary man. Men in sedentary occupations are more likely to develop coronary heart disease and, since this is caused by atherosclerosis, physical inactivity may influence its development or progression. The increased rhythmic expansion and contraction of the arteries during exercise may aid the pickup of lipids filtering through the vessel wall by lymph channels.

Occupation appears to influence atherogenesis, I believe indirectly. Perhaps it is that successful businessmen become successful because they have more drive—a preponderance of androgens over estrogens. Or with the mental stress of recurring minor crises, the effect of increased output of corticoids and intermittent elevations of blood pressure may play a part in atherogenesis. Finally, it may be that their living and eating habits result in an increased intake of fats. The increased incidence of atherosclerosis in middle-aged career soldiers is possibly related to the high content of fat in the Army ration.

The influence of fat in the diet has been considered in most countries of the world as an important factor in atherogenesis. The evidence, briefly, is as follows: In Norway during the war years, 1940 to 1945, during a marked curtailment of fat in the

diet, a sharp reduction in the incidence of deaths from coronary, cerebral, and generalized arteriosclerosis was reported. The reduction was approximately 50 per cent. From England a 50 per cent reduction of mortality in diabetics over the age of 45 is reported since the government instituted the rationing of fat at the onset of the last war. Over 100,000 diabetics in England alone have had their lives saved. Similar reports, though less impressive, come from France, Italy, Sweden, Finland, and Denmark.¹² Scattered reports of series of patients treated in this country by a low-fat diet in general favor the reduction of fat along with an over-all lowering of the caloric intake in the treatment of coronary atherosclerosis.^{9,12,13} My own experience indicates excess fat intake to be one of the environmental factors which accelerates onset and progression of atherosclerosis. This is still controversial, however. Two recent studies not only present additional data reflecting the adverse influence of fats in the diet of patients with coronary occlusion, but they also lend support to the belief that the low-fat diet results in prolonged lowering of blood lipids. In the study by Roen,¹⁴ 82 per cent of the total initial drop in serum cholesterol was maintained in 50 patients. The period of treatment at the time of the report was from 2½ to 4½ years. Unfortunately, ages were not given. The study from the University of California by Lyon and associates¹⁵ was most complete and gave a follow-up study for a 5-year period of 351 patients with myocardial infarction and 119 patients with angina pectoris. In patients who did not adhere to a low-fat, low-cholesterol diet, the recurrence and death rate was 4 times as high as in patients who adhered to the diet. The low-fat, low-cholesterol diet was found to be effective in maintaining chronically lowered lipoprotein atherogenic index values.

Further information concerning the effect of a prolonged low-fat diet in maintaining a prolonged lowering of plasma cholesterol may be obtained from studies on repatriated American prisoners of the Korean conflict. During "Operation Little Switch" I was one of a group in a position to make certain studies which were published.¹⁶ Serum cholesterol was run on 67 consecutive American prisoners within 24 hours of release by the enemy. The average value was 151 mg per 100 ml, including four with high levels compatible with familial hypercholesteremia. These four were in the range of 500 to 600 mg per 100 ml. None of the remaining 63 were above 250 mg per 100 ml. Twenty-four had values below 130 mg per 100 ml. These men had been on low-fat, low-caloric diets for two to three years. The mean value of cholesterol done on serum of 25 nonprisoner soldiers at the same time by the same laboratory* was 219 mg per 100 ml.

*U. S. Army Tokyo General Laboratory

HEREDITY

Administration of methyltestosterone has been shown to alter the lipoproteins of serum in that the alpha levels are reduced and the beta levels are elevated. This is thought to be due to the androgenic influence on hepatic function.

Clinical trials of estrogens in males following coronary occlusion have shown increased protection from second occlusions.¹⁴ The gynecomastia, loss of libido, and impotence were deterring complications in the earlier trials. However, trials with smaller dosages of different estrogens reportedly have resulted in minimizing the unfavorable side effects while retaining the protective action. The essence of a great deal of work with the sex hormones is that testosterone increases the beta lipoproteins. Estrogens are efficacious only insofar as they inhibit testicular androgen production, primarily via pituitary gonadotrophic inhibition and secondarily by neutralizing the circulating androgen. They have no effect in the postmenopausal atherosclerotic female, but are helpful in the premenopausal diabetic female in whom hypo-ovarianism is common. After castration, estrogen functions solely as an adrenal androgen depressant.¹⁵

Eleven relatively young men were currently under treatment for atherosclerotic heart disease in the outpatient facilities of this hospital. Their ages ranged from 32 to 52 years, 5 being under 40. Because of the seriousness of coronary disease in this age group, a trial on estrogen therapy was felt to be justified. A 75-year-old man with carcinoma of the prostate, who had had an orchidectomy, was added for interest. Plasma lipoprotein levels of alpha, beta, S₁ 12-20, and S₁ 20-100 fractions were done at the Walter Reed Army Institute of Research. After the initial determinations, each patient was treated with 0.02 mg of ethinyl estradiol daily for seven weeks. The plasma lipoprotein fractions were again determined, and individual values are shown in table 1. The results were altogether inconclusive. The treatment caused no undesirable symptoms during this period. Estrogen was discontinued. Low-fat, low-cholesterol diets were prescribed for all, and some were started on heparin sodium therapy. After using heparin sodium in a few for familiarization, it is planned to treat most of these men biweekly with 150 to 250 mg of concentrated aqueous heparin sodium subcutaneously for its plasma lipid-clearing action. The laboratory studies will be repeated later at 24- and 48-hour intervals following the previous injection.

Present studies of the cause of atherosclerosis have placed most of the emphasis upon an abnormal elevation of various lipid fractions, the levels of which are affected by patterns of heredity as well as by certain disease states and the increased ingestion of dietary fats. Atherosclerosis, particularly the coronary type, runs in families and represents a mild form of hereditary dis-

turbance of lipid metabolism. Alvord,¹¹ for instance, found that 15 members of one family had hyperlipomina, 6 had xanthoma tuberosum, and 18 had a history suggesting disease of the coronary arteries. A recent survey¹² of a group of Navajo Indians showed albumin to be lower than normal, and alpha and gamma globulin elevated. Alpha and beta lipoproteins were low, but other lipoproteins were normal. Total cholesterol values were considerably lower than what we consider to be normal. Since diet was the same as that given to the non-Indian control group, heredity appeared to be the most likely explanation for the different values found. The Navajos have a low incidence of coronary disease. Idiopathic hypercholesteremia may be produced by a single dominant gene. This could determine an individual's capacities and the nature of his reaction under specific conditions. Causative hereditary and environmental factors co-exist and are by no means mutually exclusive.

Men with the body type of prominent muscularity, compactness, and "maleness," the so-called mesomorphic type, are most likely to develop coronary disease at a younger age. Obviously, mesomorphy is hardly a remediable condition, but it is possible that diet and other measures may prevent the early onset of coronary atherosclerosis in this group.

Certain races appear to be prone to atherosclerosis regardless of diet. The Jews are perhaps the best example of this. Do Jewish males produce more testosterone and/or less heparin than, for example, Eskimos, who on a high-fat diet have a low incidence of atherosclerosis? Or is the anatomy, biochemistry, and physiology of the vessel wall, all of which are hereditarily conditioned, different in different races?

Studies of mast cells, which produce heparin, have shown decreased numbers of these cells in atherosclerosis, along with decreased amounts of circulating heparin. A recent report from the Cedars of Lebanon Hospital, Los Angeles, Calif.,³ may indicate the importance of heparin sodium in the treatment as well as the development of atherosclerosis. One hundred and five patients with known previous myocardial infarctions were given 200 mg of aqueous heparin sodium subcutaneously twice weekly. One hundred and seventeen alternate patients with the same diagnosis and in the same age group were given injections of saline solution. Treatment was given for from 6 to 18 months, and at the end of 2 years there were 21 deaths due to cardiovascular disease in the control group and 4 in the heparin sodium-treated group. Symptomatic improvement occurred in 25 to 35 per cent of the controls and in 50 to 75 per cent of the treated group. These workers found that this dose of heparin sodium significantly lowered the blood level of low-density lipoproteins in these patients for as long as 24 to 36 hours and in some for as long as 72 hours.³

TABLE 1. Blood lipid values in 12 patients with coronary heart disease

Clinical data						Lipoproteins (mg/100 ml) before estrogen therapy				After 7 weeks of 0.02 mg ethinyl estradiol daily			
Patient	Age	Diagnosis	Months since onset	Other diseases	Total cholesterol	Alpha lipo-protein (76-142)*	Beta lipo-protein (61-189)	S _f 12-20 (43-51)	S _f 20-100 (72-84)	Alpha lipo-protein	Beta lipo-protein	S _f 12-20	S _f 20-100

— : Abnormal values

In all studies of the infiltration of vascular walls by lipids, time is an important factor. Thus, if the injection of heparin sodium is followed by a marked though temporary reduction of the low density lipoproteins, a transformation from high S_1 to lower S_1 lipoproteins, as reported by several workers,^{1,2,20} considerable time may elapse even after the serum lipoproteins have reached their preheparin levels before substantial amounts again penetrate into the arterial walls. Furthermore, macromolecules form films upon the surfaces of the cells and the vascular intima, and, because of their inability to escape through the pores, would be most likely to form fat sludges on the endothelium. Since it is precisely these larger fat particles which almost disappear following an adequate dose of heparin sodium, the harmful effects of intimal films—prevention of normal molecular exchange between the plasma and interstitial fluid, and the accumulation in the subendothelial tissues—should be substantially ameliorated by heparin sodium therapy. Reformation of films should take longer than the reaccumulation of plasma lipoproteins.

Finally, the beta lipoproteins have been found to interfere with glucose uptake in muscle. Their lowered concentration following heparin sodium therapy may permit more normal carbohydrate metabolism in diabetes.⁵ This may be vital to heart muscles barely getting enough blood through a narrowed coronary artery.

Heparin sodium may be valuable in preventing platelet agglutination on the cement substance of injured endothelium, which may be the initial step in thrombosis. This is aside from its general anticoagulant action.

Heparin sodium may be used for years with no greater risk of hematoma formation or bleeding than the diabetic's risk from insulin reactions. In fact, insulin dosage should be lowered if heparin sodium is used in a patient taking insulin, since not as much is required.

A great number of investigators favor the use of heparin sodium as an anticoagulant in the prolonged treatment of impending or acute coronary occlusion because of its greater safety, dependability, and the relatively little laboratory control it requires, as well as for its lipid-clearing action.²¹⁻²³ This latter may prove to be vital, as ultracentrifugal studies have demonstrated that lipemic clearing is the result of a shift of serum lipoproteins from larger to smaller, less harmful particles.²⁴ Of more immediate clinical importance, however, is the recent appreciation that alimentary lipemia is associated with increased coagulability of the blood,²⁵ increased platelet adhesiveness and aggregation of erythrocytes, and an increase in viscosity.²⁶⁻²⁸

SUMMARY AND CONCLUSIONS

The evidence is fairly conclusive that the circulating lipoproteins are the source of the increased lipids found in atherosclerotic vascular walls. The physical state and particle size of the lipoproteins are important, probably due to the filtration properties of the vessel walls.

Studies of numbers of mast cells in animals and humans, and of circulating heparin levels, indicate that decreased heparin production in the body may be etiologically important in the accumulation of large amounts of circulating low-density serum lipoproteins.

An unfavorable chemical balance of androgen over estrogen often results in increased levels of beta lipoproteins, which appears to be the prerequisite to atherogenesis. Treatment of 12 patients with 0.02 mg of ethinyl estradiol daily for seven weeks failed to produce consistent laboratory improvement.

Factors such as hypertension, diabetes mellitus, nephrosis, myxedema, local factors in the vascular wall, race, and eating habits unfavorably influence atherosclerosis.

ACKNOWLEDGMENT: The author wishes to thank Col. W. D. Graham, MC, USA, for co-ordinating the laboratory work required and assisting in the preparation of this article.

PSYCHIATRIC PREDICTION AND MILITARY EFFECTIVENESS

Part II*

ALBERT J. GLASS, *Colonel, MC, USA*

FRANCIS J. RYAN, *Captain, MSC, USA*

ARDIE LUBIN, *Ph. D.*

C. V. RAMANA

ANTHONY C. TUCKER, *Colonel, MSC, USA*

THE FIRST part of this study demonstrated that when psychiatrists estimated the future effectiveness of recent inductees, their predictions of satisfactory duty were usually correct, but they were unable to efficiently identify the potentially unsatisfactory soldier. However, there still was the possibility that various components of the mental examination may be more accurate indicators of future unsatisfactory service than the over-all impression of the psychiatrist. For example, if it were found that parental disharmony in the formative years or a poor school record was highly correlated with inadequate military duty, psychiatric selection could be made more efficient by properly weighing the positive history of such developmental events. In order to test this assumption, separate elements of the psychiatric examination were compared to military effectiveness.**

FAMILY HISTORY AND MILITARY PERFORMANCE

A major portion of the psychiatric examination was devoted to circumstances of the early formative environment. Included in this sphere was the psychiatric status of parents and siblings as reported by the subjects. Family members were rated as mentally disturbed if there was a history of psychosis, neurosis, or clear-cut personality disorder. Symptoms of a clear-cut personality disorder included alcoholism, seclusiveness, and anti-social behavior. Table 12 indicates a small but significant relationship between psychiatric abnormalities in siblings and

*Part I was published in the October 1956 issue of this Journal.

From Walter Reed Army Institute of Research, Walter Reed Army Medical Center, Washington, D. C.

unsatisfactory military performance. The influence of mental disturbance in the mother is similar but less striking, although still statistically significant. Psychiatric abnormality of the father was unrelated to military effectiveness.

Another component of the family history concerned the absence of one or both parents because of death, divorce, or severe chronic illness. It is reasonable to believe that inductees from so-called "broken homes" are more apt to become marginal or poor soldiers than individuals who originate from "normal" homes. This hypothesis was tested in table 12 with negative results. Similar inconclusive findings were obtained when the influence of substitute parents upon military performance was explored.

Conflict between parents is usually regarded as deleterious to adequate childhood development. However, table 12 reveals that parental disharmony was not related to military effectiveness. Negative results were also obtained when the influence of overt sibling rivalry upon later duty performance was considered.

The psychiatric examination also recorded the attitude of the subjects toward their parents. Most subjects gave conventional responses of normal positive feelings toward father and mother. The small minority who expressed deviant attitudes of over-attachment, resentment, or ambivalence did not exhibit a significant diminution of military function (table 12).

Economic status of the family during the formative years may play a role in the formation of adult patterns of behavior. Parental economic status was rated as marginal or relief only if difficult financial conditions persisted for two or more years. Table 12 demonstrates that this aspect of family history was statistically related to military effectiveness.

It can be postulated that past or current assimilation difficulties of foreign-born subjects or subjects with foreign-born parents may hinder adjustment to the new military environment. In measuring the effect of cultural differences upon ability to function in the Army, table 12 reveals that this apparent handicap was not a barrier to satisfactory duty.

The influence of religion in the home also was explored for its relationship to military effectiveness. A majority of subjects studied stated that religion was a positive force in the childhood home. The remainder reported religion to be of little or no importance in their formative years. As shown in table 12, this aspect of the early environment did not significantly alter military effectiveness.

The position of the individual in the family constellation in relation to other siblings has been cited as pertinent in the

development of personality traits such as aggressiveness, dependency, and the like. This question is considered in table 13, and the results indicate that family position had no significance insofar as military performance was concerned.

TABLE 13. *Position in sibling constellation and military performance**

Position	Number	Per cent satisfactory duty
Youngest, only boy, or only child	230	90
Eldest child or eldest boy	176	88
Middle or other child	99	88

*Level of statistical significance .5

To recapitulate, this study could establish little or no relationship between environmental circumstances of the past as related by the subjects and their military performance. These rather negative results do not negate commonly held beliefs that early experiences influence later adult behavioral patterns. The results do indicate that retrospective and subjective accounts of the past as given by subjects under conditions of psychiatric evaluation in this or similar studies were not valid indicators of military performance. Moreover, although the death of parents, financial hardship, and position in the family are factual, it apparently is the impact of these events upon the individual that is of more significance for later behavior than is their mere occurrence.

PRESERVICE ADJUSTMENT AND MILITARY PERFORMANCE

The second major section of the standardized psychiatric examination dealt with behavior of the subject prior to induction. The first item in this area concerned the individual's adjustment to the family. Adjustment was rated as questionable or impaired if the subject (1) left home before the end of adolescence, (2) quarrelled incessantly with parents or siblings, or (3) was overly dependent upon the family, unable to make independent decisions, et cetera.

Table 14 indicates a small but significant relationship between faulty family adjustment and unsatisfactory military duty.

Another element of preservice behavior involved sexual adjustment. A rating of questionable or impaired adjustment in this sphere was given if there was a history of: (1) repressed sexual drive as manifested by avoidance of the opposite sex, lack of sexual activity, or disgust and overly moral attitudes; (2) exces-

sive preoccupation with sex over an extended period; or (3) persistent overt homosexual desires or activity.

TABLE 14. *Preservice adjustment and military performance*

Area of maladjustment	Satisfactory duty				Statistical significance
	Positive history		Negative history		
	No.	%	No.	%	
Parental family	86	80	419	91	.01
Sex	124	89	381	89	NS*
School	152	80	353	93	.001
Work	71	76	434	91	.001
Social and recreational life	79	80	426	91	.01
Community	36	67	469	91	.001

*No significance

As demonstrated in table 14, inadequate sexual adjustment was not related to military effectiveness. This finding is not surprising since the sexual drive is usually in a state of flux during early adult life. Thus it was difficult to establish valid criteria of sexual normalcy for the young subjects of this study.

Tangible evidence of achievement and conformity in a structured environment is represented by the school record, which should be a good indicator of future military performance. School adjustment was rated as questionable or impaired if there was a history of (1) consistent failure of the subject to apply himself to his academic task; (2) marked failure to associate with fellow students; or (3) serious disciplinary difficulties with teachers.

As expected, this criterion was significantly correlated with military performance (table 14).

The work record is another objective past accomplishment which involves tasks and obligations similar to that imposed by military service. However, most of the youthful subjects in this study had relatively little time in which to establish patterns of work behavior. A rating of questionable or impaired work adjustment was given if there was (1) floating from job to job; (2) repeated discharges from jobs; (3) chronic difficulties with fellow employees or superiors; or (4) failure to work when opportunities are available.

Based on the above criteria, table 14 reveals that the work record, even in young subjects, was significantly related to military effectiveness.

In assessing social and recreational adjustment, the examining psychiatrists were requested to take into account all interpersonal relationships not centered upon home, work, school, or sex. Impairment in this category was considered present if there was evidence of (1) seclusive, withdrawn behavior; (2) overly aggressive or hostile behavior toward others; or (3) absence of any recreational life.

Table 14 indicates that *maladjustment in this area* was also statistically correlated with military performance.

The last category of preservice behavior concerned adjustment to the community. A rating of maladjustment was given if there had occurred (1) overt crimes of one kind or another; or (2) *trouble-making short of criminal behavior*, such as public brawling, obnoxious behavior, when drunk, et cetera.

Table 14 revealed that antisocial behavior was the most significant preservice indicator of unsatisfactory military duty. Because of past and present induction standards which exclude persons who have been convicted of a felony, there were relatively few subjects who were rated as having impaired community adjustment.

It is apparent from table 14 that preservice adjustment is a more efficient predictor of later military performance than the category of family history. Yet it should not be forgotten that the bulk of subjects who were considered maladjusted in any area of preservice behavior did render satisfactory duty. Therefore a positive history of such deviant behavior can only indicate an increased probability of noneffective military functioning rather than a valid reason for psychiatric rejection.

It was not possible to improve the efficiency of prediction by adding two or more criteria of preservice adjustment. The number of subjects who were rated as maladjusted in several areas were too few for accurate statistical analysis. Also little additive benefits were achieved by combining two or more criteria of impaired preservice behavior since the same phenomenon was measured; namely, maladjustment to the preservice environment as represented by school, work, or the community.

PSYCHOPATHOLOGY AND MILITARY PERFORMANCE

The standard examination form required the psychiatrist to record his clinical impression regarding the extent of psychopathology that was found, in relation to the following categories:

1. Well integrated.

2. *Neurotic personality*—used to designate neurotic traits or immature reactions which did not disable or incapacitate.

3. Suggestive neurosis—for suggestive psychogenic somatization reactions, immature reactions, or long-standing neurotic symptoms, where there is no clear-cut incapacity or illness.

4. Overt neurosis—where incapacity has resulted from neurotic traits or symptoms.

5. Pathologic personality—includes excessive seclusiveness, anti-social behavior, sexual deviations, and definite pathologic behavior in interpersonal relations with none of the above neurotic patterns.

6. Latent or overt psychosis.

Table 15 indicates that as the severity of psychopathologic symptoms as diagnosed by the psychiatrist increases, military effectiveness decreases. The "well integrated" category, signifying an absence of deviant history or abnormal findings, identifies a superior group in which 90 per cent or more rendered effective service. The performances of those with borderline or mild abnormalities such as "neurotic personality" and "suggestive neurosis" were only somewhat less effective than the average

TABLE 15. *Psychopathology and military performance**

Category	Number of inductees	Per cent performing satisfactory duty
Well integrated	273	93
Neurotic personality	131	88
Suggestive neurosis	38	84
Pathologic personality	38	81
Overt neurosis	22	68
Latent and overt psychosis	3	0
Total group	505	89

*Level of statistical significance .001

of the entire group. An interesting result was obtained in the "pathologic personality" group. Although this category includes aggressive, impulsive persons who frequently resort to anti-social behavior and usually have a marginal or poor preservice record, over 80 per cent of those so classified performed useful military service. Although these individuals are often considered to be poor garrison or peacetime soldiers, this finding confirms

the general impression of many psychiatrists that aggressive, unstable personnel often perform creditably under combat and other wartime circumstances. The group judged as having "overt neurosis" had preservice or current disabling neurotic illness. It is noteworthy that two thirds of these subjects rendered satisfactory duty. It is difficult to form firm conclusions from the three individuals who were diagnosed as having latent or overt psychoses. When psychopathologic symptoms are severe and grossly evident, such men should be rejected for military service. However, none of the three subjects were discharged as clinically psychotic. They did exhibit inadequate behavior, and two received administrative types of discharge for unsuitability.

INTELLIGENCE AND MILITARY PERFORMANCE

Intellectual ability is a traditional measuring device of fitness for both civilian employment and military duty. In order to qualify for military service, selectees must be morally fit, obtain a required score on the Armed Forces Qualification Test (AFQT), and meet prescribed medical standards. The usual rejection rates for each requirement are indicated by the results of preinduction examinations during the first year of the Korean conflict (table 16).

TABLE 16. Results of preinduction examinations under the Selective Service Extension Act of 1950¹⁴
(July 1950 through June 1951)

Results of examination	Per cent of inductees
Not acceptable	
For medical reasons only	15.0
Failed AFQT and medical	3.9
Failed AFQT only	15.2
Administrative disqualification*	1.0
Acceptable	64.9

*Morally unfit, based on previous criminal behavior in most cases.

From the above data, it is clear that failure to pass the AFQT is a major cause of disqualification for military service. Essentially a modified intelligence test battery, the AFQT was introduced in 1950 to meet the needs of the three armed services for a single standard designed to estimate learning potential. Under this standard, individuals could be classified according to their

ability to absorb military training. From the AFQT score, the following groups were devised:

Group	Percentile score
1	93-100
2	65-92
3	31-64
4	10-30
5	0-9

Persons who score in group 5 are generally rejected for military service because they are considered untrainable by the usual methods of military instruction. In practice some selectees who failed to score above group 5 were "administratively" accepted. These were individuals whose AFQT score was inconsistent with their educational and work attainments or individuals whose motivation for the test was presumed poor.

The material of this study provided an opportunity to assay the usefulness of the AFQT in predicting military performance. Approximately 11 per cent of the subjects scored in group 5 of the AFQT. These subjects must be regarded as representing a superior level of those who failed the AFQT, since there must have been educational, work achievement, or other factors which influenced induction officials to accept them. It is believed that the performance of group 5 subjects in this study could provide some indication of the potential military usefulness of others who failed the AFQT and were thereby eliminated at induction. The relationship of AFQT results and performance is shown in table 17.

TABLE 17. AFQT results and military performance*

Group	Number	Per cent giving satisfactory service**
1	47	94
2	98	95
3	150	90
4	148	86
5	58	80

*Level of statistical significance .001

**Four cases unknown

These results demonstrate a significant positive relationship of the AFQT groupings to military performance, but ability of the AFQT to identify potential unsatisfactory soldiers is questionable since 80 per cent of group 5 subjects rendered adequate duty. In this respect the AFQT did not demonstrate any greater accuracy than several elements of the psychiatric examination.

It is of interest to compare the efficiency of the AFQT with other measures of intellectual capacity. The examining psychiatrists in this study also rated the intelligence of each subject by the clinical impression that was obtained at the interview.

From the results shown in table 18 it is evident that intelligence as judged by the psychiatrist was also significantly related to military effectiveness. However, except for the small number considered to be deficient, clinical estimation of the subjects' intelligence was less efficient than the AFQT.

TABLE 18. *Clinical estimation of intelligence and military performance**

Category	Number	Per cent giving satisfactory duty
Definitely superior	38	95
Average or above (not superior)	360	91
Below average	95	81
Deficient	12	58

*Level of statistical significance .001

Another measure of intelligence is educational attainment. Table 19 indicates that low educational attainment (0 to 7th

TABLE 19. *Educational attainment and military performance**

Educational level completed	Number	Per cent giving satisfactory duty
High school or better (12 or more grades)	298	95
9th to 11th grade	115	84
8th grade	48	83
0 to 7th grade	44	68

*Level of statistical significance .001

grade) was a better predictor of unsatisfactory performance than the corresponding group 5 of the AFQT. High educational level and AFQT groups 1 and 2 were equally effective in the selection of a superior group who rendered 95 per cent satisfactory duty. However, educational criteria placed 298 subjects in the superior group in contrast to only 145 subjects in groups 1 and 2 of the AFQT score. Scholastic achievement is more than an index of endowed and acquired knowledge, for it is also a valid record of prior adjustment in a disciplined and structured environment. Success in school requires not only intellectual ability but reasonable compliance to authority, some capacity to tolerate frustration, and sufficient maturity to relinquish immediate goals for later and more socially desirable objectives, all of which are similar to requirements for adequate adjustment in a military setting.

COMMENTS AND CONCLUSIONS

This study tested a major and unresolved question in military psychiatry; namely, can qualified psychiatrists, given a reasonable period of interview time, efficiently predict the future military usefulness of newly inducted draftees or enlistees? Psychiatric selection as such was not directly investigated since the subjects who participated in the project had been medically screened and otherwise found acceptable for military service. Nevertheless, the results of this study are pertinent to the problems of psychiatric selection, for the following reasons: (1) If it is demonstrated that psychiatric impressions are obtained at the inception of military service and are found to have little or no predictive relationship with subsequent performance, these data would constitute strong evidence for doubting the practical value of psychiatric screening. (2) If certain components of the mental examination are found to be more significantly correlated with military effectiveness than the over-all impression of the psychiatrist, the proper use of this information could enhance the reliability of psychiatric selection methods.

The results of this study can be summarized by the following conclusions:

1. *Psychiatric and psychologic criteria were unable to efficiently identify the potentially unsatisfactory soldier.*

Only 25 per cent of the psychiatrist's predictions of unsatisfactory service proved to be correct, whereas their estimations of satisfactory duty achieved 90 per cent accuracy. Similar results were obtained by training officer prediction, the AFQT score, and several items of the psychiatric examination. This relative inability to properly identify the potential military failure can be ascribed to one or more of the following inherent sources of error in psychiatric prediction.

Efficient psychiatric screening requires an unusually high degree of accuracy. As demonstrated in this study and similar investigations, 85 to 90 per cent of military personnel render adequate service. It is necessary to obtain 95 per cent or better correct predictions in order to justify rejection for psychiatric reasons, except in those individuals who are obviously unfit by virtue of gross mental defect or disease. Thus, from a purely statistical standpoint, psychiatric selection faces a formidable task. Only a small minority of candidates can be rejected, and these individuals must have a strong likelihood of noneffective performance, regardless of assignment or other circumstances.

The element of time markedly influences the accuracy of prediction for unsatisfactory service. When the future military performance of inductees is estimated for a long duration of time (over 6 months), there is a sharp decrease in the number of correct predictions for below-average and poor duty. This effect of time is clearly illustrated in table 8 (Part 1) of this study, in which 8 of the 9 subjects who were judged to render poor function in the Zone of the Interior are correctly identified. All of these military failures occurred in the initial five months of service, and three subjects were being processed for discharge at the time of the psychiatric examination. In sharp contrast were the results of prediction for overseas and combat assignments which involved subjects who had completed five to six months of training. In these groups, forecasts of unsatisfactory performance were rarely correct (tables 4 through 7, Part 1). It is evident that gross errors in estimating long-term military adjustment are inevitable since a sufficiency of time permits environmental changes and other situational circumstances to exert a profound influence on motivation and behavior which cannot be predetermined. Because of the foregoing reasons, psychiatrists can hope to make valid predictions of unsatisfactory service only for brief periods of time under known and relatively uniform environmental conditions, such as the training phase.

Professional differences among psychiatrists influence prediction. The six examining psychiatrists of this study, although fully qualified by training and experience, nevertheless exhibited individual patterns of predicting military performance. Among the psychiatrists there was considerable variation in both the type and proportion of subjects estimated to render unsatisfactory duty. This aspect of psychiatric selection will be more fully explored in a later report.

2. Psychiatric criteria can identify groups of varying military effectiveness.

The results of this study indicate that relative degrees of predisposition or adaptability to military stress can be demon-

strated in groups of individuals. Certain psychologic and sociological data that include school and work record; educational attainment; community, social, and recreational adjustment; the AFQT; judgment of line officers, and the clinical impression of the psychiatrist were found to be significantly related to military performance. By using any of the foregoing criteria, inductees could be classified into one of the following categories (based upon percentage of effective individuals); namely, (1) superior, from 90 to 95 per cent; (2) average, from 80 to 90 per cent; and (3) inferior, from 70 to 80 per cent.

Predictors that contained some measurement of intellectual ability provided the most practical index of potential military effectiveness. This conclusion is supported by findings that school record, educational level, the AFQT, and intelligence ratings by psychiatrists are highly correlated with each other and as individual rating devices gave better predictive relationships to military performance than other background data. Educational attainment was perhaps the best predictor of the intellectual measures. This information achieved a useful discrimination among the subjects for it placed the largest proportion (60 per cent of the total) in a superior group and correctly predicted the highest percentage of unsatisfactory duty in the inferior category (tables 17 through 19). Moreover, educational level is a relatively simple and concrete type of information that can be obtained from the inductee with a minimum of distortion, although, admittedly, standards of education do vary in the various geographic regions of the United States.

That inductee or selectee groups of varying efficiency can be identified by psychiatric data has also been demonstrated by Aita⁸ and others.^{9,10,11} Indeed it is this aspect of psychiatric prediction which has given rise to the optimistic statements made by Wittson and Hunt¹² regarding the validity and usefulness of psychiatric screening. Their contentions may be correct if the objective of psychiatric selection is to insure the largest proportion of effective servicemen without regard for the number of potentially satisfactory individuals who will be eliminated by such a process. Screening procedures of this type may be justified in the selection of officer candidates or men for highly specialized tasks, or in maintaining a relatively small cadre type Army where the limited number of individuals required make it profitable to exclude "inferior" or even "average" categories. Also, rejectees under such a program are not necessarily lost to the service. However, the huge manpower requirements of a general mobilization will not permit the losses that would occur if predisposition standards such as outlined above were put in practice. For example, in "inferior" groups the removal of three potential failures

would also eliminate seven others who were capable of satisfactory military service. In order to meet the needs of the armed services during wartime, psychiatric selection methods must be sufficiently accurate to identify an inferior group, more than 50 per cent of whom will inevitably become a burden to the military effort.

SUMMARY

Psychiatrists, the AFQT, and various components of the mental examination were unable to efficiently identify potential military failures. From the standpoint of general mobilization, these results indicate that further investigative efforts should be undertaken during this peacetime era in order to insure more accurate methods of psychiatric screening because they will be vitally needed in the event of another major conflict.

ACKNOWLEDGMENT: The authors are grateful to Mrs. Evelyn Bowman for her help in gathering the data, and to M/Sgt. Herman A. Becker for his help in the statistical computations.

THE "COMMON" MAN

"The patient who is a living detective-story may also be, I suggested, a poem of many parts that can, from time to time, reflect the light of sublimity. This you may find hard to credit when you examine some shrivelled little man with hammer-toes and a smoker's cough; but even he, even the most drably insignificant of your patients, will have had some experience of the wonder and mystery in which we live, and confidently he can expect more. He was born, and he will die; and no one who has seen birth and death can deny that 'fearfully and wonderfully are we made,' or dispute the mystery that envelops us and, at the end, gives to the meanest a moment of dignity.

CUP AND REPLACEMENT ARTHROPLASTIES

Experiences in an Army Hospital

JAMES D. CASKIE, *Lieutenant Colonel, MC, USA*
JOSEPH W. BATCH, *Colonel, MC, USA*

SINCE the popularization of hip arthroplasty with the vitallium cup method of Smith-Petersen,¹ and more recently with the replacement prosthesis methods of Judet,² Eicher,³ Moore,⁴ Thomson,⁵ Naden-Rieth,⁶ and others,⁷⁻¹⁰ much has been written on each of these methods as a means of treating various conditions affecting the hip joint. The study herein reported was undertaken to compare the various methods employed in this hospital, where individual orthopedic surgeons have used different methods of arthroplasty.

TABLE 1. *Pathologic hip conditions treated at Brooke Army Hospital (1949-1955)*

Hip condition	Number
Fractures (all kinds)	224
Aseptic necrosis	10
Nonunion, fractures	39
Dislocations, traumatic	93
Dislocations, congenital	72
Ankylosis	49
Gunshot wounds	13
Arthritis	23
Tumors	5
Degenerative joint disease	5
Total	583

From 1949 through 1955, 583 pathologic conditions involving the hip joint were encountered (table 1). Of these 583 hip conditions, 43 (in 40 patients) were deemed amenable to treatment with 19 cup and 24 replacement prosthesis arthroplasties. The conditions for which these arthroplasties were performed are listed in table 2.

From Brooke Army Hospital, Fort Sam Houston, Tex. Lt. Col. Caskie is now assigned to Fitzsimons Army Hospital, Denver, Colo.

TABLE 2. *Conditions for which cup or replacement arthroplasties were performed*

Pathologic fracture, neck of femur	1	
Total	19	24

INDICATIONS

Initially in this series, cup arthroplasties were employed exclusively; during the early 1950's replacement prostheses began to be utilized; and more recently, with a crystallization of indications for the type of treatment, cup and replacement prostheses have been utilized about equally.

In general, whenever only the head of the femur was damaged, cup arthroplasty was employed. A Judet type prosthesis was used when the condition of the head precluded nailing, bone graft, and osteotomy and where sufficient length of neck remained. When the head and neck were destroyed, an intramedullary type of prosthesis was employed (table 3).

TABLE 3. *Types of arthroplasties performed by years*

Year	Cup	Judet	Thomson	Moore	Eicher	Naden-Rieth
1949-1950	6					
1950-1951	3	4				
1951-1952	3	8				
1952-1953	1		1	3	1*	
1953-1954	3	1		1		1
1954-1955	3			3		1
Total	19	13	1	7	1	2

*This replaced one of the Judet prostheses inserted during 1950-1951.

The principal conditions for which cup arthroplasties were performed were aseptic necrosis of the femoral head, traumatic arthritis, and osteoarthritis. Prostheses were utilized primarily

for fresh, comminuted fractures of the head of the femur in the younger age group; fresh, comminuted fractures of the head and neck in the older age group; and persistent nonunion of fractures of the neck of the femur. The earlier prostheses were of the Judet type, more recently only the metallic replacement prosthesis has been employed.

There was one patient in the 50-60 year age group with bilateral cup arthroplasty, one patient in the 20-30 year age group with a bilateral Judet prosthesis, and one patient in whom an original Judet prosthesis was replaced with an Eicher prosthesis. This Judet prosthesis, originally inserted for traumatic arthritis, was an early nylon type which on removal showed marked roughening of the head portion and areas that appeared to have been worn down as if sandpapered during joint motion. Seventeen patients were female and 23 were male, with an average age of 33.8 years in the cup group and 49.4 years in the prosthesis group (table 4).

A variety of approaches and modifications were employed, but the posterolateral approach was considered to be more functional, technically easier, and less traumatic, allowing earlier rehabilitation.

COMPLICATIONS AND FOLLOW-UPS

In this series of 43 operations performed on 40 patients, 4 patients were lost to follow-up. Sixteen patients with 17 cup arthroplasties have been followed an average of 31.8 months, and 20 patients with 22 replacement prostheses have been followed an average of 29.7 months (table 5).

There were 28 complications—12 in the cup arthroplasty group and 16 in the prosthetic replacement group. The complications, which compare favorably in number and type with other similar series,^{11,12} are listed in table 6. They include 3 dislocations of the hip, 4 fractures of the neck or trochanter including 1 fracture dislocation in a Judet prosthesis, 2 cases of thrombophlebitis, 2 sciatic nerve injuries, and 4 infections or reinfections. Three of these were reinfections in old septic hips, which in two cases ultimately resulted in satisfactory ankylosis. There were no deaths in the series, although two patients have subsequently died—one patient four years after insertion of a Judet prosthesis and the other one nine months after the insertion of a Moore prosthesis. Pain, although listed as a complication, was slight in nature in three patients and was not a major factor resulting in limitation of motion or function. One patient with a Moore prosthesis was entirely relieved of pain by an obturator neurectomy. In the five fractures that were encountered, three occurred in the reduction of the prosthesis at time of surgery and two resulted from falls. There was one fracture dislocation in which the fracture eventually healed with the Judet prosthesis dislocated. The

TABLE 4. Types of arthroplasties performed by age of patient

Age of patient (years)	Cup		Naden-Rieth		Judet		Moore		Eicher		Thomson		Total
	Male	Female	Male	Female	Male	Female	Male	Female	Male	Female	Male	Female	
0-10													
10-20	2	1				2				1			2
20-30	4	2		1	2		1				1		10
30-40	1				1								6
40-50	4				1	1		1					6
50-60	3		1		2	3	1	1					7
60-70	1	1				1	1	1					8
70-80													4
Subtotal	15	4	1	1	6	7	3	4		1		1	43
Total	19		2		13		7		1		1		43

remaining fractures healed, but two resulted in marked limitation of motion, one in a cup arthroplasty and one in a Judet prosthesis. The remaining dislocations produced no problems other than the required secondary reduction, and both ultimately showed excellent results. Both patients in whom thrombophlebitis was a complication recovered; one returned to duty and was capable of playing 18 holes of golf.

TABLE 5. *Average follow-up time*

Duration of follow-up (months)	Type of arthroplasty	
	Cup	Protheses
6	1	3
12	2	1
24	6	7
36	2	5
48	3	2
60	2	2

TABLE 6. *Complications*

Complication	Type of arthroplasty					Total
	Cup	Judet	Moore	Eicher	Thomson	
Pain	1	1		1		3
Dislocation	1	1			1	3
Infection	3				1	4
Fracture, neck of trochanter	1	2	1			4
Shortening (1 inch plus)	2	2				4
Fracture, femur, in fall	1					1
Thrombophlebitis		1	1			2
Limitation of motion	2					2
Sciatic nerve injury	1	1				2
Arthritis		1				1
Myositis ossificans		2				2
Total	12	11	2	1	2	28

RESULTS

In spite of a large number of complications, the final results in the follow-up cases were satisfactory (table 7). In the prosthetic replacement group, 86.3 per cent, and in the cup arthroplasty group, 76.4 per cent were considered to have excellent or good results. In evaluating the end results, range of motion, gait, freedom from pain and limp, and functional capacity were considered. The average range of motion of the hip in patients

with a prosthesis was 85° of flexion and 19° of abduction. In those patients who had a cup arthroplasty, the average range of motion was 89° of flexion and 21° of abduction. One patient with a Judet prosthesis and one patient with a cup arthroplasty complained unusually of pain and limp, but in both cases there was shortening of more than 1 inch. The patient with the Judet prosthesis obtained marked relief and improvement in gait after a lift was applied to the shoe. One patient with cup arthroplasty who had 2½ inches of shortening was given a 1-inch shoe lift, with marked improvement in gait and decrease in pain. This patient returned to duty as a traction and cast-room technician. Two patients with sciatic nerve damage walked well with foot-drop spring braces. One of them recovered totally and after two years discarded his brace.

TABLE 7. *Results of arthroplasties*

Type of arthroplasty	Result					Total
	Excellent	Good	Fair	Poor	No follow-up	
Moore	4	2	1			7
Eicher	1					1
Thomson		1				1
Naden-Rieth	2					2
Judet	5	4		2	2	13
Cup	9	4		4	2	19
Total	21	11	1	6	4	43

SUMMARY

Of a total of 563 pathologic hip conditions, 43 conditions in 40 patients were treated by cup or prosthetic replacement arthroplasties. Although a large number of complications were encountered, the end results in both the prosthetic replacement and cup arthroplasty groups were considered satisfactory. This was particularly true when the proper surgical procedure was selected for the indications present in the individual patient, with consideration of cup arthroplasty in the younger age group and prosthetic replacement in the older age group.

FRACTURES OF THE FIRST RIB

"In dealing with closed thoracic injuries, especially those produced by high speed automotive accidents, one is obligated to search carefully for evidence of first rib fracture, which may be easily overlooked before callus formation begins.

"Patients suffering such fractures, without early manifestations of mediastinal lesion, must be thoroughly examined at frequent intervals; for at least two years following injury. Each examination should include an x-ray of the chest.

"Widening of the superior mediastinal shadow in the vicinity of the aortic arch following chest injury should be considered a sign of possible incomplete rupture of the aorta, or other great vessel, from which aneurysm may develop."

ON THE READING OF MEDICAL LITERATURE

With Remarks on "The Derailment of Reason"

ALAN GREGG, M. D.

WHEN I was a student in Harvard Medical School, in 1915, I was piqued because I heard frequent praise of the Harvard Law School and rarely anything comparable regarding the Medical School. So I decided to cut my classes for three days and go to Law School lectures. It was worth it. I was surprised and deeply impressed to see how much attention was given in the Law School to learning *how* to think, as contrasted with learning *what* to think. In essence it seemed that the difference was between the dynamic and the static—how to think prepared you for the future, what to think recorded the past.

I have begun with this story and the distinction between learning how to think and learning what to think, because I believe that the cardinal requirement for effective reading of medical literature is discrimination, and discrimination depends directly on learning how to think. Even today our medical schools pay little or no attention to this essential skill.

In 1928 the organizer of the British Medical Research Council, Sir Walter Fletcher, asked me, "What do you think about the medical curriculum?" It appeared clear to him that the factual additions to knowledge made by medical science had already passed the capabilities of even the best students to master in four years, and there was no reason to suppose either that the important facts would become fewer, or that another year or two could be added to the medical school's share in the preparation for medicine. He thought that the only solution would be found in a totally fresh review of medical education and the curriculum thereof. He suggested that attention be given first of all to choosing the capacities or abilities essential to every practitioner, researcher, or teacher. Once these capacities had been agreed on, we could devote the curriculum to strengthening and refining them, leaving to the years of practical clinical or laboratory experience as much as possible of the memorizing of facts and the acquirement of skill.

Presented as the Fifth Annual Harold Wellington Smith Guest Lecture, U. S. Naval Medical School, Bethesda, Md., 28 April 1955.

Dr. Gregg was for 21 years Director for the Medical Sciences and now is Vice President of The Rockefeller Foundation, 49 W. 49th St., New York 20, N. Y.

I do not remember whether he named these capacities, but after long reflection I would suggest that they are these: the capacity to observe, the capacity to reason from your own observations, the ability to compare your observations and reasoning with the observations and reasoning of others, and, at quite a different level of performance, the ability to put yourself in the place of the patient—to acquire or develop compassion. You can readily see that the capacity to read medical literature forms a large share of the task of comparing your observations and reasoning with that of others, and let me add that the best—not the *only*, but the *best*—time to read medical literature is after you have done some observing and reasoning of your own, and not as a substitute for it.

When I say reading I mean critical reading. Even as you read this sentence (if you are a discriminating reader) you will say "critical of whom and of what?" My answer would be: critical of the author, whoever he be, and of his reasoning as well. The classic definition of rhetoric throws delightful light on this problem, for it says, "Rhetoric is the art of conveying conviction without resort to logic." Shades of the Detail Men! What a deft warning! It is even possible that if you begin by learning to read other people's writing critically you may thereby learn, even though it be at long last, to be effectively critical of what you yourself say and write.

The question "critical of what?" puts its roots into a larger area and to a greater depth. I have found much illumination in a remark attributed to Oscar Wilde to the effect that "all criticism is a form of autobiography." For example, General von Blücher's critical appraisal of Paris tells us more about Blücher than it *does of Paris*. He said of Paris, "*Was für plündern!*" We are usually only half aware of how often and how much our past individual experience affects our capacity to evaluate as well as to reason. Nor do we always realize the subtlety of such influences; they often supply us with major assumptions that are quick and plausible but completely wrong. The physician who bases his conclusions on the experience of civilian practice can disagree both honestly and correctly with a colleague whose practice in the Armed Forces has given him a radically different experience.

Scarcely ever can one find a mountain that looks the same from the north as it does from the south. Reality is like that; it has many aspects and can only be fully portrayed by views that are not identical nor even similar, because they are views from different points of the compass. Here appears the major argument for reading; namely, that it makes available to you glimpses of truth that you have not seen. In binocular vision or a stereoscopic camera, the two images are not identical; and from the very fact

that they are *not* the same, a new sense, that of distance, becomes possible. The gains from reading usually come from the contrast between what the author has observed or concluded and what you have noted and inferred.

But sometimes you read about work in a field of which you have had no experience. What then? Well, rather obviously, you are in that case in need of a clear and comprehensible exposition, rather than the type Lord Balfour had in mind when he spoke of "things that would have been clearer if they had not been explained." Authors whom I find worth reading use description and narration to tell what something is, and definitions to tell what it is not. The hallmarks of a good exposition are that it translates or formulates *the less familiar into terms that are more familiar*; it translates *the obscure into the clear, the variant into the constant, the complex into the simple, the vague into the precise, forms into functions, and states into forces*.

Before expanding such a condensed statement and to anticipate your possible objection that you don't see how all this can bear upon the question of how to read medical literature, let me say that if an author follows none of these requirements in the first few pages of his article, I save a wonderful amount of time by refusing to read further. With the almost fantastic amount of reading we all should do, knowing what not to read becomes a cardinal point of progress in the general task of learning how to read. Some sort of selection is necessary, and I find that it is better to base one's reading on the quality of the author's mind than to select it on the title or the field of his experience. I would therefore suggest a few particulars to keep in mind when you start to read a scientific article.

First, an author of a scientific article fails in his purpose if he puts his ideas, even though they may be familiar to him, into terms that are quite unfamiliar to most of his readers. (There is one qualification to be made on this point that I will mention later.) I saw once in a psychoanalytic journal this statement: "Music is pure libido symbolism lacking objectification or cathexis." And some of you will remember Dr. Johnson's definition of a cough as "a spasm of the diaphragm vellicated by some sharp serosity." It is the reader's need—if not his right—to have the unfamiliar made familiar and the obscure made clear.

Another desideratum in medical literature is that the constant be shown as lying behind the variant. The capacity to detect and to convey this kind of clarification often improves as a result of some measure of sophistication in regard to the mathematics of probability. I would be glad to see solid geometry disappear from secondary and college curricula in favor of an equally rigorous study of the mathematics of probability, and would welcome

a wider acquaintance on the part of medical scientists with rhythmic and cyclical phenomena and the technics of detecting their occurrence and their intervals. F. R. Dewey and his associates are doing pioneer work in this field that for the most part appears in "Cycles," a monthly report of the Foundation for the Study of Cycles.

The scientific mind so frequently simplifies the complex by means of a formula, that if an article you read performs exactly the opposite and makes the simple more complicated, it deserves to be regarded with suspicion. I am less certain regarding two more characteristics of a good scientific article, perhaps because they are rarely to be found, rather than because they are trivial. Indeed they are anything but trivial. When form can be translated into terms of function, or states of being into terms of forces, we are near the cutting edge of the scimitar of science.

Lastly, one of the most important functions of good medical literature is to render the vague more precise. The psychologist, E. B. Holt, said, "A word that has many connotations denotes nothing, and a word that denotes anything cannot have connotations." For example, the word water has many connotations, but H_2O denotes just one chemical compound. Experience in putting that dictum to the test has suggested to me the thesis that one of the essential differences between scientific language and literary language consists of the fact that scientists express themselves in denotative terms, and literary artists—particularly the poets—have mastered the connotations of words.

Now all these comments point to an exceedingly interesting subject, namely notational systems. Many sciences develop their own signs and symbols, and unless we become thoroughly familiar with the notational system of a particular science, we find reading it extremely tiring and are all too ready to declare that what we read as beginners fails completely to put the less familiar into the more familiar, the complex into the simple, the obscure into the clear, the connotative into denotative terms, the variant into the constant, or the vague into the precise. Getting accustomed to symbols requires much effort, but using them effectively rewards the user remarkably. For this reason, we usually do not stop to wonder whether the symbols are really adequate for their purpose, forgetting that explanations in a notational system that is not adapted to the subject to be explained become needlessly complicated and hard to grasp. Think of trying to record the operations of the Stock Exchange in musical notation! It seems to me that there are at least two fields, endocrinology and serology, where we have not yet found the right type of symbols or denotative terms for the kind of thinking that is needed.

True familiarity with the symbols involved in some branch of science serves to protect us from glibness in using them. Not

long ago Mr. Fred McNamara of the Bureau of the Budget asked me if I knew what a billion dollars was. I replied that I could write the figure and that the word billion has one meaning in Europe and quite a different one in North America, but that I really did not know what a billion dollars was, so he told me: "A packet of a thousand \$1,000 dollar bills eight inches high is a million dollars; a billion dollars is a pile of \$1,000 bills 111 feet higher than the Washington Monument." For all its precision and its effectiveness, the decimal notation tempts one to glibness—and incomprehension.

Much could be said about notational systems and how they work, but perhaps their best effect is in drawing our attention to the kind of thinking that we use in medical science. Because I believe that explicit attention to this thinking will provide the most valuable ways to read or refuse to read medical literature, I would like to explore a little further our methods of making observations and sensible inferences. Probably a brief narrative will serve my purpose.

When I was taking the introductory course in pathology in 1913, I had the good fortune to have Dr. Howard Karsner as a teacher. Dr. Karsner, then as now, could pack a formidable amount of information into a very short space of time when he lectured, and I was disturbed by my failure to write fast enough to keep up with what he was saying. One night I had the somewhat vain-glorious idea that if one Gregg could invent a shorthand system, why couldn't another? So I devised symbols for organs and organ tissues, and for such concepts as atrophy, hypertrophy, infiltration, inflammation, induration, and necrosis, and found that they covered the nouns most in use. The adjectives needed related to size, form, weight, position, staining properties, and consistency, together with such concepts as normal and abnormal, acute and chronic, rare and frequent. The adverbs referring to time (quickly or slowly), to quantity, and to frequency were the commonest adverbs used in pathology. The most commonly used verbs were: *causes* or *is caused by*, *follows* or *is followed by*, *shows* or *is found*, *is accompanied by*, *contains* or *is found in*. To my surprise and considerable interest, these nouns, adjectives, adverbs, and verbs usually conveyed a substantial part of the concepts and the statements of an introductory course in pathology.

Soon after this invigorating discovery came a haunting disappointment. Statements put into my shorthand were clear but they were not cogent. They were comprehensible but not convincing. What was wrong? The answer to that question did not come quickly, but it contained, I think, the best sieve through which to sift the first page or two of anything you read, if you want to test the author's reliability. It deals with what adjectives

and adverbs you have a right to expect in almost any serious writing in the medical sciences.

Consider the statement: "Mosquitoes transmit malaria." Of such a statement one can say that it reports a brilliant discovery and that it is profoundly true and important, but also one can say that as a statement it is distressingly unsatisfactory. What is needed are qualifying modifiers such as *all* or *some*, for both the subject and object. For the verb, such modifiers as *always* or *sometimes* may be required. Finally, the word *only* may be needed as a modifier for subject, verb, or object. When the correctly selected qualifying words have been put in, you have something cogent, resembling cabinet work rather than three logs lashed together with a liana vine. The accurate choice of the correct modifiers of the subject, verb, and object in the case of the unchallengeable statement, "mosquitoes transmit malaria," makes the final statement conclusive as well as clear. Broadly speaking, if you pick up a reprint and the subjects, predicates, and objects have no qualifiers of the above-mentioned sort, you are not in first-class intellectual company, and you proceed with the reading at your own risk. So much for the best sieve I know of for separating the wheat from the chaff in medical literature.

One of the most frequent purposes of scientific papers relates to finding the causes of some phenomenon or condition, but most medical scientists seem completely oblivious (or ignorant) of the fact that results usually come from many causes, not one. I doubt if I could exaggerate my feelings regarding the stupidity we show in so frequently assuming that one result is due to only one cause. We ought to use the word *why* in the plural and ask, "Whys is this patient in coma?" not, "Why is this patient in coma?" The next time you hear someone say anything that attributes a single cause for some event, ask yourself if he means the predisposing, the precipitating, or the perpetuating cause? And how many causes of each of these kinds are involved? A particular case of a fractured jaw in a sailor may be the result of convergent causes—no letters from home, too much alcohol, the loan of a car by a friend, a dark night, an oncoming car on a road covered with ice at a curve, the fact that the left-hand rule is used in the British Isles, new brake linings, a skid, and a telephone pole. These constitute the whys, not the why, of a fractured jaw. It is a cataract of consequences. Take out any one of these whys and the accident would not have occurred. When will we wake up to the importance of multiple causation? Some prefer to call it convergent causation. I am as sorry for those physicians who have never heard of "Occam's Razor" as I am for those who have never heard of Gillette's.

Whenever you hear it stated that A causes B, you can get a sort of intellectual setting up drill by saying to yourself, "I

long ago Mr. Fred McNamara of the Bureau of the Budget asked me if I know what a billion dollars was. I replied that I could write the figure and that the word billion has one meaning in Europe and quite a different one in North America, but that I really did not know what a billion dollars was, so he told me: "A packet of a thousand \$1,000 dollar bills eight inches high is a million dollars; a billion dollars is a pile of \$1,000 bills 111 feet higher than the Washington Monument." A particular case of a fractured jaw in a sailor may be the result of convergent causes—no letters from home, too much alcohol, the loan of a car by a friend, a dark night, an oncoming car on a road covered with ice at a curve, the fact that the left-hand rule is used in the British Isles, new brake linings, a skid, and a telephone pole. These constitute the whys, not the why, of a fractured jaw. It is a cataract of consequences. Take out any one of these whys and the accident would not have occurred. When will we wake up to the importance of multiple causation? Some prefer to call it convergent causation. I am as sorry for those physicians who have never heard of "Occam's Razor" as I am for those who have never heard of Gillette's.

Whenever you hear it stated that A causes B, you can get a sort of intellectual setting up drill by saying to yourself, "I

wonder if it isn't wiser to say that B causes A?" For example, it is fairly probable that in the next six months you will hear it said that some acquaintance "has had a nervous breakdown from overwork." Ah! There is an implication that overwork has caused a nervous breakdown. How would it be to reverse the interpretation and conclude that the man overworked because of self-doubt or overconscientiousness, which are early symptoms of some kinds of oncoming nervous breakdowns? Perhaps depression or insecurity inclined him to stay at the office until a quarter of eight instead of quitting at five o'clock as he used to . . . and then to a quarter of ten, and then to midnight. And at a later stage, when he had exhausted his sense of fatigue, staying all night at work. I have found this particular form of mental gymnastics not only diverting but at times remarkably rewarding—which is more than I could honestly say of the usual kind of gymnastics.

Quite naturally, if we are unaware of the frequency of multiple causation, we are the easy victims of plausibility; we stop looking for more than one cause if the one that occurs to us seems plausible. Let me give you, to illustrate the subtle way in which plausibility can kill true curiosity, an experience that I will disguise by changing the scene to a distant city. I was attending a medical lecture in Liverpool, England, given by an Irish physician. He failed to hold my attention. I began to watch a device behind the speaker which flashed the names of doctors in the audience who were wanted on the telephone. I noted that an unusually large number of the names were Irish; 17 out of 19. Now 13 out of 19 would not have been above the probabilities of chance, but 17 out of 19 was well above being a chance event. What could explain that? Being amused by the number of plausible explanations, I listed them. Here is the list, and any one of the reasons might have seemed so plausible as to stop any further inquiry:

1. The Irish population in Liverpool is unusually large.
2. The medical profession in Liverpool contains a very high proportion of Irishmen.
3. Irish doctors are notably conscientious about keeping up with advances in medicine by attending lectures.
4. Irish doctors want to be seen attending lectures.
5. Irish doctors are unusually compassionate and ready to sacrifice even such opportunities as professional lectures to the whims of their patients.
6. Irish physicians employ nurses who need close supervision or who are excessively conscientious.
7. The patients of Irish physicians want their money's worth and are not phlegmatic or submissive.

8. The lecture hall was in the Irish sector of Liverpool.

9. Irish doctors flocked to hear the lecturer because he was an Irishman and a graduate of the National at Dublin.

10. The Irish doctors in Liverpool want their names to be better known and crave the appearance of being busy.

11. The lecture was on a disease very common among Irish people.

12. The prestige of the Irish doctors in Liverpool has become so great that English physicians are changing their names—for, mark you, all I was seeing was Irish *names*, not necessarily Irish *men*.

As a last remark on the risks of mere plausibility, let me call your attention to the fact that all these circumstances *might* have been true simultaneously.

As another example of plausibility, let us assume that a substance not frequently found in urine has been reported in one of your patients. Among the plausible explanations are: (1) It was ingested and when present is routinely excreted by the kidneys. (2) It is normally present in the blood and is usually put out only by a so-called leaky kidney. (3) It is normally stored in the bones and has been released by the ingestion of some other substance, *e. g.*, lead released from the long bones by the ingestion of large quantities of phosphoric acid. (4) It is usually excreted by some other organ such as the lungs or the skin, but this mechanism is interfered with and the kidney takes over the task. (5) It was not ingested but is the product of faulty metabolism, *e. g.*, an adrenal neoplasm. (6) There was another patient with the same name and the specimens were mixed.

From these examples you can see that an article in any current journal that fails to list all of the plausible explanations for an event should show cause for limiting its attention to just one of them.

Let us pass from the pitfalls of plausibility to the equally misleading failures due to an ignorance of the laws of probability. We cannot rely upon good horse sense in such matters. What do you think are the probabilities that at a dinner attended by 20 people there will be at least one pair who share the same day of the same month as their birthday? Are you surprised to know that it is better than a 50-50 chance? More precisely it is a 52.05 chance. Does that disturb your confidence in your common sense? It did mine.

The commonest failure I note in most medical articles is the assumption that in a short series of cases, say 41, a positive result in 26 is evidence of something more than chance. I can offer you in this connection a simple formula the mathematician R. A. Fisher gave me as a reliable criterion for drawing sound

inferences from small numbers, *i. e.*, a good working rule to apply. Let the total number of cases be called $a + b$, a standing for the number of positives and b the number of negatives. You are reasonably safe if $\frac{(a - b)^2}{a + b}$ equals 4 or more. Thus, in a series

of 41 cases, if 26 are positives and 15 are negatives, the result works out to only 2.9, and 26 out of 41 is not significant because it does not significantly exceed mere chance. But if there had been 27 positives and 14 negatives, then $\frac{(a - b)^2}{a + b}$ would have

equaled 4, which begins to be significant. This formula is readily applied to many a medical report, and I have found it a valuable criterion to apply in reading case reports.

Some day you may have time to kill. Flip a penny 1,500 times and keep a record of the results. I did this once and got 755 heads and 745 tails. Very reassuring! But in that series I had one run of 12 heads in succession. Supposing that a run of 12 successive cures, or at least remissions, should be observed when first using a new drug for patients with multiple sclerosis. How could one fail to become a convert to such a drug? It is a very sobering reflection, and has led me to believe that one of the great needs of medicine, and particularly for men in research work, is a course in evidence. Intensive drill in distinguishing between hunches, surmises, varying degrees of probability, and the nature of certainty or proof could be an extraordinarily valuable experience for most of us.

One more suggestion and I am through. When a train wreck occurs, the railroad officials want to find out the whys and the hows: was it due to a defective rail, roadbed, bridge, signal, item of rolling stock, or human reaction? Now, when as medical scientists we try to keep our thinking, observations, and inferences on the right track, we too are fatefully subject to one or another kind of derailment of our reasoning. The different kinds of the derailment of reasoning deserve closer study than they are getting. Indeed, I had thought of entitling this lecture, "The Derailment of Reason," but I thought that if I could call it, "On the Reading of Medical Literature," I could interest you first in the errors of others' thinking and then you could, with these errors in mind, turn your attention in slow crescendo to the mistakes that all of us make. Moreover, a new kind of approach lies at hand. The history of medicine is loaded with false interpretations of biologic phenomena, inferences that were but derailments of reasoning. Clinical observations have been wonderfully good, in comparison to the inferences drawn. Let us study, clarify, and classify such derailments of interpretation or reasoning, in order to improve our performance in keeping on the track. For as George Santayana said, "He who is disposed to ignore history must be prepared to repeat it."

CONCURRENCE IN PSYCHIATRIC DIAGNOSIS

WILLIAM A. BUNT, *Commander, MSC, USN*
CECIL L. WITSON, *Commander, MC, USN*

THE QUESTION of diagnostic concurrence, or agreement among psychiatrists, is one that has concerned us in our continuing study of the theory and practice of naval psychiatric selection.^{1,2} Since the diagnostic process is basic to any selection procedure, we have considered its implications^{3,4} and experimentally studied some of its characteristics.^{5,6} This article compares the diagnoses given a group of recruits under psychiatric observation during basic training with the diagnoses assigned when they were subsequently discharged during later active duty. It not only studies diagnostic agreement among psychiatrists, but offers further information on the discharge channels typical of different types of psychiatric cases.

PROCEDURE

During World War II those recruits undergoing basic training at the Newport Naval Training Center who were suspected of serious psychiatric involvement were admitted to the observation ward of the psychiatric unit for careful study before disposition. Those borderline patients considered capable of rendering adequate service were returned to active duty. Subsequently many of these received psychiatric discharges from the fleet, offering an opportunity of comparing the discharge diagnosis with that assigned on the observation ward at Newport. The present experimental sample thus consists of men diagnosed on the observation ward at Newport, sent to duty, and subsequently discharged during service with the fleet. It should be stressed that all these were borderline cases and therefore presumably more difficult to diagnose.^{7,8} Also, the Newport diagnosis was not entered in the health record and thus could not have prejudiced the final discharge diagnosis. Moreover, the time elapsing between the original diagnosis and ultimate discharge ran in some cases to as long as three years.

Since the psychiatrists on the Newport ward were not held to any specific diagnostic nomenclature while the final fleet diagnosis had to conform to official naval nomenclature, it was felt that any comparison involving specific, detailed diagnoses would

This study is part of a larger project being conducted through the Department of Psychology of Northwestern University, Evanston, Ill., under contract with the Office of Naval Research.

inferences from small numbers, *i. e.*, a good working rule to apply. Let the total number of cases be called $a + b$, a standing for the number of positives and b the number of negatives. You are reasonably safe if $\frac{(a - b)^2}{a + b}$ equals 4 or more. Thus, in a series of 41 cases, if 26 are positives and 15 are negatives, the result works out to only 2.9, and 26 out of 41 is not significant because it does not significantly exceed mere chance. But if there had been 27 positives and 14 negatives, then $\frac{(a - b)^2}{a + b}$ would have equaled 4, which begins to be significant. This formula is readily applied to many a medical report, and I have found it a valuable criterion to apply in reading case reports.

Some day you may have time to kill. Flip a penny 1,500 times and keep a record of the results. I did this once and got 755 heads and 745 tails. Very reassuring! Let us study, clarify, and classify such derailments of interpretation or reasoning, in order to improve our performance in keeping on the track. For as George Santayana said, "He who is disposed to ignore history must be prepared to repeat it."

CONCURRENCE IN PSYCHIATRIC DIAGNOSIS

WILLIAM A. HUNY, *Commander, MC, USN*
CICIL L. WHITE, *Commander, MC, USN*

THE QUESTION of diagnostic concurrence, or agreement among psychiatrists, is one that has concerned us in our continuing study of the theory and practice of naval psychiatric selection.^{1,2} Since the diagnostic process is basic to any selection procedure, we have considered its implications^{3,4} and experimentally studied some of its characteristics.^{5,6} This article compares the diagnoses given a group of recruits under psychiatric observation during basic training with the diagnoses assigned when they were subsequently discharged during later active duty. It not only studies diagnostic agreement among psychiatrists, but offers further information on the discharge channels typical of different types of psychiatric cases.

PROCEDURE

During World War II those recruits undergoing basic training at the Newport Naval Training Center who were suspected of serious psychiatric involvement were admitted to the observation ward of the psychiatric unit for careful study before disposition. Those borderline patients considered capable of rendering adequate service were returned to active duty. Subsequently many of these received psychiatric discharges from the fleet, offering an opportunity of comparing the discharge diagnosis with that assigned on the observation ward at Newport. The present experimental sample thus consists of men diagnosed on the observation ward at Newport, sent to duty, and subsequently discharged during service with the fleet. It should be stressed that all these were borderline cases and therefore presumably more difficult to diagnose.^{7,8} Also, the Newport diagnosis was not entered in the health record and thus could not have prejudiced the final discharge diagnosis. Moreover, the time elapsing between the original diagnosis and ultimate discharge ran in some cases to as long as three years.

Since the psychiatrists on the Newport ward were not held to any specific diagnostic nomenclature while the final fleet diagnosis had to conform to official naval nomenclature, it was felt that any comparison involving specific, detailed diagnoses would

This study is part of a larger project being conducted through the Department of Psychology of Northwestern University, Evanston, Ill., under contract with the Office of Naval Research.

be unfair. For comparison we therefore selected the broad categories of psychoneurosis (PN) and personality disorder (PD). It would have been desirable to include a psychotic category, but all men falling in this category were automatically discharged at Newport and none were sent on to the fleet. No organic cases were included in the study. Since disciplinary and general medical discharges are also known disposal outlets for psychiatric involvement, we included such final fleet discharges in our study, hoping that interesting differences in our groups might appear. Thus, the criteria for inclusion in the sample studied were that the man must have been diagnosed on the observation ward during basic training at Newport, subsequently sent to duty, and later discharged from the fleet for psychiatric, medical, or disciplinary reasons.

The sample studied consisted of 82 recruits originally diagnosed as psychoneurotic and 213 diagnosed as having a personality disorder. As a control we included 28 men showing symptoms of psychoneurosis, such as anxiety, tachycardia, tremor, depression, et cetera, but whose symptoms were not sufficiently pronounced to permit them to be definitely diagnosed as psychoneurotic; and 82 men showing symptoms typical of the personality disorders, such as immaturity, history of many arrests, nomadism, et cetera, but who were not definitely diagnosable as such. Also included as a control were 40 men studied on the observation ward and judged to be normal.

RESULTS

The results are presented in table 1, which gives the percentage of each original diagnostic group falling in each of the final discharge categories. Comparing the original with the final psychiatric diagnosis, we find that of all the cases originally diagnosed as psychoneurotic and subsequently receiving a psychiatric discharge from the fleet, approximately one half received a diagnosis of psychoneurosis, with the majority of the remainder being discharged as personality disorders. In view of the borderline nature of the cases and the amount of time elapsing between the original and the final diagnosis, the diagnostic agreement would seem to be fair and would indicate some efficiency in the original diagnostic performance. Some confusion obviously exists between the psychoneurotic and personality disorder categories, however. These results are confirmed by the group which showed psychoneurotic symptoms but which could not be definitely diagnosed as psychoneurotic. Turning to the group with personality disorders, we find that approximately three quarters of those subsequently receiving a psychiatric discharge were discharged as personality disorders. Again, this is confirmed by the group with only symptoms of a personality disorder. The agreement here is certainly good. It would appear

that the diagnosis of personality disorder is a more reliable one than that of psychoneurosis, a finding that confirms those of a previous study of ours.⁶ The personality disorders seem to be more reliably identified than the psychoneuroses.

TABLE 1. Agreement between Newport diagnosis and final discharge diagnosis

Newport diagnosis	Number of diagnoses	Percentage subsequent diagnosis					
		PN*	PD**	PN+PD***	Other	Medical	Disciplinary
Psychoneurosis	82	27	26	1	4	7	35
Psychoneurotic symptoms	25	44	12	0	2	3	39
Personality disorder	213	9	20	2	4	41	24
Personality disorder symptoms	82	7	32	0	4	17	40
Normal controls	42	5	5	5	5	12	67

*PN = Psychoneurosis

**PD = Personality disorder

***PN+PD = All disciplinary discharges

When we look at the other medical and disciplinary discharges, we find some interesting differences between the groups. The psychoneurotics are significantly less apt to receive a disciplinary discharge than are the men with personality disorders, who show a marked tendency to disciplinary difficulties. The psychoneurotics are even less of a disciplinary problem than the normal men. On the other hand, the psychoneurotics tend to be more of a medical problem than those with personality disorders. These findings confirm another investigation by us.⁷ Moreover, these differences are in agreement with the clinical interpretation of the disorders and show that the psychiatric diagnosis predicts important aspects of the individual's social behavior. As would be expected by the definition of "normal," psychiatric and disciplinary discharges are relatively infrequent outlets for our normal control group.

These findings on disciplinary and medical discharges demonstrate the importance of considering these disposal channels in any study of the psychiatric serviceability of military personnel. They also raise a question concerning the study of the reliability of psychiatric diagnosis; i. e., if a recruit is diagnosed as an asocial personality and subsequently receives a bad conduct discharge, or if he is diagnosed as psychoneurotic and subsequently receives a medical discharge for some psychosomatic complaint, are not these examples of diagnostic concurrence rather than the disagreement superficially implied by the difference in the channels of disposal?

SUMMARY

The study of a group of recruits, originally diagnosed as having psychoneurotic or personality disorders but subsequently sent to duty as borderline cases, who were later discharged from the fleet for psychiatric, other medical, or disciplinary reasons shows close concurrence in psychiatric diagnosis. As compared with the psychoneurotics, the patients with personality disorders were much more of a disciplinary problem and somewhat less of a medical problem.

THE SHIFTING INCIDENCE OF PSYCHOSIS

Manic-depressive psychosis and general paresis are definitely on the decline since about 1935. Rates for general paresis are much higher for men than women, but the relative difference is less in recent years than formerly. Manic-depressive psychosis rates are higher for women than men. Alcoholic psychosis shows some exceptions, a generally rising incidence, with rates that are very much higher for men than for women.

TECHNIC OF CREMASTER MUSCLE DISSECTION IN INGUINAL HERNIOPLASTY

FELIX P. BALLENGER, *Captain, MC, USN*

THE PROPER method of dissecting the cremaster muscle when performing inguinal hernioplasty has been little discussed, yet in many cases it presents a real problem if an adequate repair is to be accomplished. In performing inguinal hernioplasties, and also when observing other surgeons performing this operation, I have noted difficulty in accurately suturing the fascia of the transversalis muscle to the shelving border of the inguinal ligament about the spermatic cord at the internal inguinal ring when the usual methods of dissection of the cremaster fibers were used. If the cremaster fibers are split in the line of their descent, or if they are allowed to continue to encircle or cover the cord structures in any manner, they will invariably obstruct the proper placement of sutures about the spermatic cord at the internal inguinal ring.

OPERATIVE TECHNIC

In order to avoid the difficulties created by the presence of the cremaster muscle in this part of the repair, I have developed a technic for dissection in this region which completely removes the obstructions caused by the cremaster fibers, and also, in cases of recurrent hernia and large hernia, obviates excision of the cremaster in order to accomplish adequate repair. The following technic for dissection and repair of an inguinal hernia is therefore recommended, as I have used it in a large number of cases with invariable ease of suture placement and excellent results.

1. The usual inguinal skin incision is made.
2. The external oblique fascia is incised and opened in the line of its fibers into the apex of the external inguinal ring. This incision is carried about one and one-half inches above the internal abdominal ring and well down over the pubic tubercle in the external spermatic fascia.
3. The cremaster fibers are dissected free from the inguinal ligament from the pubic tubercle to one inch above the internal

SUMMARY

The study of a group of recruits, originally diagnosed as having psychoneurotic or personality disorders but subsequently sent to duty as borderline cases, who were later discharged from the fleet for psychiatric, other medical, or disciplinary reasons shows close concurrence in psychiatric diagnosis. As compared with the psychoneurotics, the patients with personality disorders were much more of a disciplinary problem and somewhat less of a medical problem.

TECHNIC OF CREMASTER MUSCLE DISSECTION IN INGUINAL HERNIOPLASTY

FELIX P. BALLENGER, *Captain, MC, USN*

THE PROPER method of dissecting the cremaster muscle when performing inguinal hernioplasty has been little discussed, yet in many cases it presents a real problem if an adequate repair is to be accomplished. In performing inguinal hernioplasties, and also when observing other surgeons performing this operation, I have noted difficulty in accurately suturing the fascia of the transversalis muscle to the shelving border of the inguinal ligament about the spermatic cord at the internal inguinal ring when the usual methods of dissection of the cremaster fibers were used. If the cremaster fibers are split in the line of their descent, or if they are allowed to continue to encircle or cover the cord structures in any manner, they will invariably obstruct the proper placement of sutures about the spermatic cord at the internal inguinal ring.

OPERATIVE TECHNIC

In order to avoid the difficulties created by the presence of the cremaster muscle in this part of the repair, I have developed a technic for dissection in this region which completely removes the obstructions caused by the cremaster fibers, and also, in cases of recurrent hernia and large hernia, obviates excision of the cremaster in order to accomplish adequate repair. The following technic for dissection and repair of an inguinal hernia is therefore recommended, as I have used it in a large number of cases with invariable ease of suture placement and excellent results.

1. The usual inguinal skin incision is made.
2. The external oblique fascia is incised and opened in the line of its fibers into the apex of the external inguinal ring. This incision is carried about one and one-half inches above the internal abdominal ring and well down over the pubic tubercle in the external spermatic fascia.
3. The cremaster fibers are dissected free from the inguinal ligament from the pubic tubercle to one inch above the internal

abdominal ring (fig. 1). It is important in this dissection to see that all fibers are completely detached from the inguinal ligament.

Figure 1. Beginning the dissection of the cremaster muscle. The point of the scissors is shown under the lower edge of the cremaster; at this site the cremaster is detached from its origin.

This lower border of the cremaster is then elevated and the dissection continued to elevate the cremaster muscle in its entirety from the external spermatic fascia and underlying cord (fig. 2). The entire cremaster, including its origin from the internal oblique muscle, is then retracted upward. This exposes the spermatic cord covered by the internal spermatic fascia (fig. 2).

4. The spermatic cord and its internal spermatic fascia covering can then be dissected completely free from the floor of the inguinal canal from the internal abdominal ring to a point below the pubic tubercle. When this has been accomplished all areolar tissue is removed from the inguinal canal and its floor (fig. 2).

5. The internal spermatic fascia is then incised in a line with the spermatic cord and the hernia sac can easily be brought up, dissected out completely, its neck transfixed and ligated high inside the internal abdominal ring, the sac excised, and the stump

allowed to retract upward. If, however, a direct hernia sac is present, it can be handled by whatever method seems appropriate such as dissection, high ligation, and excision or by imbrication and infolding.

Figure 2. The cremaster has been elevated from the cord and the cord dissected from the floor of the inguinal canal.

6. After the sac, or sacs in the case of a "Pantaloön" type, have been adequately removed or imbricated, the repair can then be proceeded with. The transversalis fascia is secured in the floor of the inguinal canal with Allis forceps, and the border of the transversalis fascia is sutured to the shelving border of the inguinal ligament with interrupted No. 00 cotton sutures (fig. 3). The sutures are placed from the medial angle lateralwards, being certain to secure the first suture into the fascia overlying the pubic tubercle. As placement of the sutures upward and outward proceeds, it becomes obvious that they can be placed on either side of the spermatic cord at the internal abdominal ring with ease without incorporating fibers of the cremaster muscle, because the cremaster and internal oblique muscles are now being retracted upward completely out of the way (figs. 3 and 4). By placing 6 to 8 sutures below and medial to the cord and 2 or 3

Figure 3. Retraction upward of cremaster muscle permits easy placement of sutures in transversalis fascia and inguinal ligament.

above or lateral to it, a snug repair around the spermatic cord usually can be obtained. In infants and children this layer of repair is not necessary and is omitted. I believe that many recurrences of indirect inguinal hernias occur because of inaccurate placement of sutures and failure to secure an adequate, snug repair about the spermatic cord. This defect can easily be avoided by using this technic of dissecting the cremaster and repairing the floor of the inguinal canal.

7. The spermatic cord is then replaced in the inguinal canal and the cremaster replaced over the cord and sutured to the inguinal ligament in its normal anatomic relationship (fig. 5). However, if it is thought desirable, the cord can be transplanted completely to the subcutaneous tissues in the Halsted repair. If the cord is replaced in the canal and the cremaster sutured over it as above described, the external oblique fascia and external spermatic fascia are then closed with interrupted No.

0000 cotton sutures and the subcutaneous tissue and skin closed with the same material. If the Halsted procedure is done the external oblique fascia is sutured beneath the spermatic cord,

Figure 4. All sutures have been tied, apposing the transversalis fascia to the inguinal ligament.

allowing the cord to emerge through this suture line at a point about one-half to three-fourths inches lateral to the internal abdominal ring. A bed of subcutaneous tissue is then sutured underneath the cord, between it and the external oblique fascia, and subcutaneous tissue and skin are closed over the cord, using No. 0000 cotton sutures throughout.

SUMMARY

A technic for dissecting the cremaster muscle from the external spermatic fascia and spermatic cord and retracting it upward along with the internal oblique muscle allows easier placement

Figure 5. The cremaster has been replaced over the cord in its normal anatomic position, and is shown here with its lower border resutured to the inguinal ligament.

of sutures in the transversalis fascia and inguinal ligament. This technic obviates the incorporation of the cremaster fibers in the suture above and lateral to the spermatic cord and, I believe, makes a more accurate and stable repair of this portion of the inguinal canal floor.

The specialist is a man who fears the other subjects.

ADVANCES IN TRAINING THE NEUROPSYCHIATRIC TECHNICIAN

DENNIE L. BRIGGS, *Lieutenant, MSC, USN*

NORMA R. WOOD, *Lieutenant, NC, USN*

CHANGING technics in the treatment of hospitalized psychiatric patients have necessitated a reassessment of the role of the nursing staff. In the past, members of the nursing staff usually considered their primary duties to be providing the custodial and housekeeping aspects of patient care, and the patient was allowed little opportunity to assist in his own treatment. Today, however, their responsibilities are centered mainly about providing an atmosphere conducive to treatment, and their duties include working with patients to a greater degree. The importance of interpersonal relations in treatment is increasingly recognized and fostered in hospitals using social psychiatric technics.

We feel that although the roles of the psychiatric nurse and the corpsman are not yet fully defined, steps should be taken to provide a continuing educational program that will give them every opportunity to learn more of treatment procedures, interpersonal relations, and the dynamics of their own personalities, and to share in developing their own niche in the treatment program. It was believed that existing educational opportunities needed revision in the light of recent developments in other hospitals and of our own experience in operating an acute admissions ward without use of restraints and with only occasional use of sedatives.¹

In a period of 10 months, approximately 1,000 patients were admitted to the acute admissions ward of this hospital, and it was not found necessary to put any patient in a seclusion room.² However, due to the fears and anxieties of various staff members, patients were put in the quiet rooms on five occasions. In order to operate such a unit, it becomes necessary to revise traditional methods of training and to provide means whereby corpsmen can learn to recognize and handle their own anxieties.

From U. S. Naval Hospital, Oakland, Calif. Lt. Briggs is now assigned to the U. S. Naval Hospital, Navy 3923, FPO, San Francisco, Calif.

CURRICULUM

The curriculum of the Neuropsychiatric Technicians School at this command has been previously described by Kahn.³ This school was established during World War II when emphasis was placed on screening out obvious psychiatric misfits and on the survey of those who had psychiatric breakdowns while on active duty.⁴ The training included highly specialized procedures such as deep insulin coma and electroconvulsive therapy and made much use of didactic lectures dealing with theories concerning the dynamics and treatment of specific mental disorders. Although there was occasional use of "milieu therapy" and brief psychotherapy, the psychiatric service and the course of instruction for technicians was primarily oriented toward physical treatment and various other suppressive and repressive technics such as sedation and restraint. In a period of less than two years the orientation changed to one in which relationship therapy was stressed on all wards, even those with acutely disturbed patients.⁵ The transition was not always an easy one, and it involved a major reorganization of the course of instruction in the school.

Formalized didactic lectures, we found, contributed to a certain kind of defensiveness on the part of the corpsman which often made him feel extremely uncomfortable, as though he was expected to interpret psychologic material to the patient. As his training was not adequate for this, he many times found himself in an extremely frustrating situation and often resorted to suppressive measures designed to control his own anxiety rather than that of the patient. This, too, was a result of his earlier medical training in which he was taught to regard the patient as a semi-invalid whose treatment involved active physical measures.

The new student has many preconceived ideas as to the nature of mental illness, the role of the technician, and exactly what composes psychiatric treatment itself. Two of our students have vividly pointed out some of these misconceptions and have shown the importance of working with the feelings and attitudes of the staff as well as those of the patient.⁶⁻⁷

One problem with which we were particularly concerned was the corpsmen's lack of participation in the patients' groups and in the ward staff meetings, and their failure to attend psychiatric staff meetings. We became convinced that, rather than stimulating them, we were contributing to their anxiety by creating an atmosphere in which they thought they had to know more than was actually expected of them.

Recognizing these needs, we instituted some time ago a weekly group discussion with the students held by a psychiatrist and

a psychologist, and more recently by the nursing supervisor, the chief of nursing service of the hospital, and a psychologist. We were rewarded by evidences of the students' growth, demonstrated by their increasing ability to express some of their feelings and anxieties. Frequently students, after working at other activities, have written us that they considered this experience to be one of the most valuable in their training.

COUNSELING PROGRAM

When the student begins his training program he is assigned to a psychiatrist on the staff for counseling purposes. If the student was formerly on the staff of this hospital, he is allowed to choose the physician he would like to work with. Students are given appointments for an initial interview; additional appointments are up to the student and the psychiatrist. In some instances students have been introduced to individual psychotherapy, which has lasted throughout their stay at this hospital and has been continued with civilian therapists after the student's release from service. These instances are most encouraging, because when the student realizes he has personal problems to cope with and seeks help with them, he is in a better position to work with patients and with staff members. The nursing instructor acts as an educational counselor as well and assists the students with their anxieties regarding their work. When educational problems become mixed with emotional difficulties, the student is encouraged to discuss these with his therapist.

More recently we have introduced two other teaching methods that have aided considerably in helping the student to take a more active part in the treatment program.

"BIG BROTHER" PROGRAM

We felt that the student needed to know patients as human beings rather than as disease entities and decided to try assigning each student a patient early in his training. The student preferably first sees the patient on one of the admissions wards and follows him throughout his stay in the hospital. He sees the patient as often as his schedule and own interest will allow with the purpose of getting to know him and finding out all he can about him. Sessions are provided for discussion of the patients, and the students are encouraged to keep notes of their contacts. At the end of the course, they prepare a summary of their impressions of the patients. Several of the patients have made marked improvement, which has served as a most effective demonstration to the student of the real value of relationships in treatment. The student provides the patient with a healthy model to identify with and feels no pressure to "treat" the patient.

At the students' request, we have modified our teaching program to include an hour per day of group discussion held by vari-

ous staff nurses to deal with the daily anxieties aroused in caring for patients. These hours have proved to be extremely rewarding, and a great deal of discussion ensues, often prolonged beyond the assigned time.

Students have chronically complained that they do not feel part of the service, and we have found that we have inadvertently contributed to this feeling by not giving them certain rights and privileges which are accorded even the most inexperienced and untrained staff members. We have taken steps to make the student feel more a part of the psychiatric service by affording him wherever possible the same opportunities as a permanent staff member. We have held seminars twice a week for the entire staff that provide an opportunity for continual growth for everyone as well as indoctrination of new staff members, and that allow as little distinction between student technicians and others as possible. We believe this will contribute greatly to the therapeutic atmosphere of the service as a whole and will result in even better patient care than in the past.

We believe that the success of methods in the newly emerging field of social psychiatry in mental hospitals justifies looking into our traditional teaching and ward management procedures and at this time see two main areas in psychiatric nursing and treatment which should be developed further.

SOCIAL THERAPY

The idea of the social therapist originated with Dr. Maxwell Jones and his work at the Social Rehabilitation Unit at Belmont Hospital in England. Here, young girls with various backgrounds are taught how to care for psychiatric patients in a relatively short period of time while working as members of the staff. They remain in the unit for only six or eight months and yet achieve a remarkably high degree of therapeutic skill. They attend a series of seminars dealing with normal growth and development given by a permanent staff member and have additional opportunities to learn about interpersonal relations in their daily contacts with patients. Their daily instruction periods enable them to deal with their own anxieties and curiosities when these are most meaningful; thus their training helps them to cope with their own problems while aiding in the treatment process. Their primary role is relating to patients and encouraging them to communicate their feelings to others in order that they may be understood and helped by other staff members and by the other patients. Pressure is thus not exerted on them to interpret psychological material.¹⁰ This orientation away from interpretation is an extremely important one, as we have pointed out.¹¹

WARD MANAGEMENT

It follows that when free communication is developed and social anxiety is lessened, both patients and the staff feel less pressure, and a truly therapeutic community can emerge. *The degree of behavioral change possible within relatively short periods of time in such an atmosphere is limited only by the abilities of the staff to share in the communication process.* The results of this kind of treatment are evident even in the chronic behavior and character disorders¹² where social rehabilitation is accomplished sometimes in four or five months, in persons with lifelong histories of great maladjustment, as well as in the debilitating neurotic disorders. One frequently hears staff members comment on the "quietness" of their ward or group, as if this were the criterion of successful treatment. Use of sedatives and restraining technics in the past created a sense of security in the staff but seldom considered the welfare of the patient.

It appears that when communication among members of the staff and between staff and patients is improved, the running of the ward itself becomes therapeutic, as the patient more and more participates in his own treatment. The staff must be able to give up some of their functions without guilt and of necessity have to "unlearn" many aspects of their roles. It is accomplished informally by dealing with anxieties as they arise.

Treatment, as we see it, consists of providing the patient with healthy people as models for his own behavior and of working out means for constant communication of his feelings to others. By healthy people we mean real people—each with his own individuality, anxieties, and interests, but free to express these qualities rather than allow them to interfere in his relationships with others. Communication increases the ability to tolerate others and to relate to them in a realistic manner, thereby decreasing the likelihood of having to act out impulses and feelings. All relationships in the hospital then become potentials for therapy if skill in using them is developed.

ACKNOWLEDGEMENTS: We would like to thank Capt. Robert R. Deen, MC, USN, Lt. Comdr. Lina Stearns, NC, USN, Lt. Margaret Shaw, NC, USN, Comdr. Myrtle Warner, NC, USN, and Dr. Irving D. Berg for encouragement, advice, and active participation in the program.

DENTAL HYGIENE AND SEX

"The real test of a patient's patience is the dental chair. Here a patient, no matter how calm he pretends to be, signals his tension by slight psychomotor movements which the dentist can detect. And, according to a dental survey made, appropriately, by *Dental Survey*, women make better dental patients than men. As a matter of fact they also take better care of their teeth generally. It seems that in pre-adolescence, little boys consider any type of washing—whether in the mouth or behind the ears—a feminine frill. Worse than that, they believe that a defiance of mother's instructions to wash the teeth, is a symbol of manliness. Then through certain psychiatric mechanisms, not to be disclosed in this family periodical, the growing boy carries this low opinion of dental hygiene right into adult life. The adolescent may slick down his hair and clean his fingernails while preparing for a date; but he apparently feels no need for washing in places where the fruit of his industry is not so visible. To the girl, on the other hand, cleanliness and body care seem to be basic virtues. All of which may account for the fact that women are better patients than men. Or are they?"

ACUTE SUPPURATIVE ARTHRITIS OF THE HIP IN CHILDREN

JAMES B. JONES, *Captain, USAF (MC)*
REGINALD C. RAMSAY, *Captain, USAF (MC)*

ACUTE suppurative arthritis is not uncommon, and in any medical facility where a large number of sick children are treated it can be anticipated that a few patients will develop a pyogenic infection of a joint. The pathogenesis is similar to acute hematogenous osteomyelitis, the bacteria being blood borne from some primary focus of infection. The offending organisms are staphylococcus, streptococcus, pneumococcus, *Hemophilus influenzae* bacillus, gonococcus, meningococcus, and occasionally coliform bacteria.¹ Any of the larger joints may be affected, but, except for gonococcal arthritis, as a rule only one of them is involved. With the present widespread use of antibiotic drugs for the treatment of primary infections, such as boils, acute tonsillitis, and otitis media, many cases of acute suppurative arthritis are either prevented or are aborted before clinical recognition is possible. When an acute inflammatory process does involve a joint, it is easily detected by signs of increased local heat, redness, swelling, tenderness, and pain on motion. However, when the hip or spine is involved the clinician must rely on more subtle findings because of the larger amount of surrounding soft tissue.

Suppurative arthritis of the hip, if neglected, has disastrous sequelae. The capitular epiphysis of the femur may be destroyed, and it is common for the hip to become dislocated.^{2,3} In other cases the articular cartilage may be destroyed, resulting in either fibrous or bony ankylosis in a position of deformity.⁴⁻⁶ It is therefore highly desirable that the diagnosis of acute suppurative arthritis of the hip be established early in its course, so that effective therapeutic measures may be instituted before irreversible changes in the joint structures can ensue.⁵ The purpose of this article is to discuss methods of early recognition of acute suppurative arthritis of the hip and to present two illustrative cases.

From U. S. Air Force Hospital, Barksdale Air Force Base, La.

SIGNS AND SYMPTOMS

The diagnosis should be considered in any child who has a fever, develops a protective limp, and refuses to walk or to move about normally. A history of a preceding febrile illness is common, or the child may still be suffering from an infection. There may be a relationship to trauma, and this is apt to be misleading. Any trauma would direct attention to the painful part but probably does not play a significant role in the pathogenesis. The patient will be irritable and restless, and will cry, especially with any movement. Inasmuch as any motion may be transmitted to the *affected hip joint*, it will be difficult for the parent and for the examiner to ascertain the site of the pain. A child of three years of age or older may be able to indicate the location of his difficulty, but if this is not the case, the physician must rely on careful observation and examination.

The capsule of the hip joint is more relaxed in the flexed, abducted, externally rotated position (the so-called "frog position"). If there is increased fluid within the joint the child will automatically tend to hold his leg in this position (fig. 1A). Any motion which will tighten the capsule and decrease the space will produce increased tension within the joint and accentuate the pain. The most important clinical finding, therefore, is the observation that the child is more comfortable with one hip held toward the frog position. With the hip supported in this position the other joints of the lower extremity can be examined without unduly upsetting the child (fig. 1B). It is especially important to rule out any disease in the knee joint. The simultaneous examination of both hips is most satisfactory (fig. 1C). By grasping the knees, the hips are held in the frog position and gently adducted and extended. Reflex muscular resistance will be detected on the affected side and the child will cry out. An uninvolved hip joint can be moved without resistance and without pain. In addition, it may be noted that *tenderness on palpation* is present over the hip joint.

These findings are indicative of increased fluid or synovial thickening within the hip joint. In children, several conditions can produce these changes. Nonspecific synovitis of the hip is the most frequent differential diagnosis to be considered. With nonspecific synovitis, not a well-understood clinical entity, the child usually does not have a fever, although frequently it occurs following a febrile illness. There is a protective limp and guarding of the hip. The signs and symptoms are not alarming and last for only a few days. One wonders if some of these cases might not be actual abortive bacterial infections.

Identical to nonspecific synovitis is the early stage of Legg-Calvé-Perthes disease, which cannot be definitely diagnosed until roentgenographic changes can be demonstrated in the capit-

Figure 1. (A) Frog position of the right hip. (B) With the hip held in the frog position, the other joints of the lower extremity can be more easily examined. (C) Simultaneous examination of both hips is most satisfactory.

ular epiphysis of the femur.' It is for this reason that all cases of nonspecific synovitis should be followed carefully and repeated roentgenographic studies made if there is persistence of any signs or symptoms referable to the hip joint. Tuberculosis, which can simulate an acute pyogenic infection, may be most difficult to rule out, and one must rely on the laboratory for final proof. Also to be considered in the differential diagnosis are rheumatoid arthritis and rheumatic fever.

Roentgenograms of the hips should be obtained in every suspected case. The capsular outline is frequently visible and, if more prominent or bulging on the affected side, is of diagnostic significance. One should also look carefully for the appearance of widening of the joint space (fig. 2). Any osseous involvement may be indicative of an osteomyelitic process.

Figure 2 (case 1). The initial roentgenogram of the hips showed widening of the joint space on the right. This is highly suggestive of increased fluid within the joint. The capsular outline cannot be visualized.

Routine laboratory studies will usually reveal a polymorphonuclear leukocytosis, although this finding was not present with one of our patients. It is to be expected that the erythrocyte sedimentation rate will be elevated.

ASPIRATION OF THE HIP JOINT

Although the diagnosis may be suspected from the foregoing, it cannot be established without aspiration of the hip joint. Not only is aspiration diagnostic, but it also is an all-important therapeutic step. Smear and culture of the joint fluid will prove or disprove the presence of a pyogenic infection, and antibiotic sensitivity studies will guide the physician in his therapeutic program.

Aspiration of the hip joint is not difficult, contrary to common opinion, and when the joint is distended with fluid, is surprisingly easy. The following method is recommended. The skin and subcutaneous tissue lateral to the femoral pulse and parallel to the prominence of the greater trochanter are infiltrated with one of the local anesthetic agents such as procaine hydrochloride or Xylocaine Hydrochloride (brand of lidocaine hydrochloride). A long 20- or 21-gage needle on a syringe filled with the local anesthetic agent is then directed toward the hip joint, keeping in mind that the head of the femur is directly beneath the femoral pulse and that the needle must angle superiorly to correspond to the normal angle produced by the neck of the femur (fig. 3).

Figure 3. The approach for needle aspiration of the hip joint.

When the needle encounters the anterior hip capsule, there is increased resistance to its insertion. By injecting small quantities of fluid, it can be determined when the hip joint has been entered. The joint space will accommodate only 1 or 2 ml of fluid, and the fluid will return into the syringe. It must be emphasized that if fluid does not return to the syringe the point of the needle does not lie within the hip joint. Frequently, if there is increased fluid within the hip joint, it will appear in the syringe as soon as the needle pierces the capsule. Before withdrawing the needle, it is wise to inject penicillin solution into the joint if there is any suspicion that a pyogenic infection is present.

All material obtained from the joint should be sent to the bacteriology laboratory for routine smear and culture. Specific ant

biotic sensitivity studies should be made. An immediate smear of the fluid may not only show the presence of pus cells, but may give an indication of the nature of the offending organism. One of the antibiotic drugs should be administered, although the culture and sensitivity studies may suggest changing to another drug at a later date.

It is beyond the scope of this article to discuss in detail the treatment of suppurative arthritis of the hip. However, in our opinion, the infection can be adequately controlled in most cases by specific antibiotic drugs if the diagnosis is established and effective drugs instituted early in the course of the disease. Surgical intervention can be held in abeyance until the efficacy of treatment with antibiotics alone can be determined. Open drainage is not to be condemned but should be used only if truly indicated.

CASE REPORTS

Case 1. A three-week-old male infant was admitted to this hospital because he had had fever, been irritable, and had not moved his right leg for one week. At the time of admission the infant cried constantly, especially on being moved about. Both hips were held flexed and externally rotated in a frog position. There was definite resistance to manipulation of both hips. However, the left could be brought to a more neutral position whereas there was increased resistance to extension of the right hip and the slightest attempt caused him to cry out. There was a one-degree temperature elevation. The white blood cell count on admission was 17,950 per μ l with 51 per cent neutrophils and 49 per cent lymphocytes. Roentgenograms of the hips showed the appearance of widening of the joint space on the right (fig. 2).

The day following admission to the hospital the right hip joint was aspirated. One milliliter of purulent fluid was obtained. Before withdrawing the needle, 450 mg (750,000 units) of crystalline penicillin G was injected into the joint space. Immediate smear of the fluid showed the presence of gram-negative intracellular diplococci. Two hundred and ninety-seven milligrams (300,000 units) of procaine penicillin G was administered intramuscularly twice daily for three days and then once daily for eight days. There was an obvious immediate improvement noted following the aspiration, and continued gradual improvement. At the time of discharge, 12 days after admission, the infant was actively moving both his legs and both hips could be brought to a neutral position without resistance.

Since discharge from the hospital the patient has been a healthy, normal appearing infant. Roentgenograms of the hips taken at age six months showed normal development of both hips.

Because of the nature of the infection the mother was examined. Urethral smear disclosed gram-negative intracellular diplococci. Treatment for her infection was therefore instituted.

Case 2. A three-year-old girl was admitted to this hospital because of pain in the right lower extremity and a protective limp. Two weeks prior to admission she had had an upper respiratory infection which resolved spontaneously. Her mother stated that four days before admission the child fell, following which she would not use her right leg when walking, and she ran a low-grade fever. The mother believed that the source of her child's difficulty was the right knee.

On admission to the hospital the child had a rectal temperature of 101°F. There was a marked protective limp on the right and the child held her right hip partially flexed and externally rotated. There was tenderness and muscle spasm about the right hip joint, and any attempt to extend and internally rotate the hip caused the patient to cry out with pain. The white blood cell count was 13,200 per μ l with 24 per cent neutrophils and 66 per cent lymphocytes.

The initial working diagnosis was synovitis of the right hip with rheumatic fever or rheumatoid arthritis to be excluded. Roentgenograms of the hips were negative. The erythrocyte sedimentation rate was 44 mm per hr, and C-reactive protein was 2 plus. Other laboratory tests, including antistreptolysin titer, blood culture, and an electrocardiogram were within normal limits. Two days after admission to the hospital salicylate therapy was instituted but the patient continued to have a temperature elevation ranging between 100° and 101°F, and no improvement in the hip was noted.

On the sixth hospital day the right hip joint was aspirated and 2 ml of slightly cloudy, straw-colored fluid was obtained. Before withdrawing the needle, 600 mg (1,000,000 units) of crystalline penicillin G was injected into the hip joint. Fifty milligrams of Terramycin (brand of oxytetracycline hydrochloride) was administered intramuscularly three times daily. The day following the aspiration the child's temperature spiked to 102°F and then she became afebrile. There was an immediate improvement in the child's clinical course.

The growth on the culture of the joint fluid was alpha hemolytic streptococcus, which was most sensitive to tetracycline and Chloromycetin (brand of chloramphenicol) and less sensitive to Terramycin and penicillin. Two hundred and fifty milligrams of tetracycline four times daily was given orally and the Terramycin was discontinued.

The patient continued to improve and on the 15th hospital day she was walking with only a slight limp. The tetracycline was continued for two weeks after the child was discharged. Clinical and radiologic findings of the right hip two months later were completely normal.

SUMMARY

The early recognition of acute suppurative arthritis of the hip is essential to avoid its disastrous sequelae.

The physician should become suspicious of this condition from the history of fever and voluntary protective immobility of the

hip. The patient often will maintain the involved hip in flexion, abduction, and external rotation ("frog position"). Widening of the joint space or bulging of the capsular outline may be noted on routine roentgenograms of the hip.

Nonspecific synovitis, rheumatic fever, rheumatoid arthritis, and tuberculous hip disease must be considered in the differential diagnosis.

The definitive diagnostic procedure in septic arthritis of the hip is aspiration of the hip joint. This should be performed in every suspected case. Bacteriologic examination of the joint fluid may reveal the specific pathogenic organism. Antibiotic sensitivity studies will guide the therapeutic program. The removal of purulent fluid from the joint space and the instillation of an antibiotic agent, such as penicillin, is highly beneficial until specific therapy may be started after completion of sensitivity studies.

VALUE OF PERSEVERANCE

"It is, however, a serious fault in a research worker to be too ready to drop problems as soon as he encounters a difficulty or gets seized by enthusiasm for another line of work. Generally speaking one should make every effort to complete an investigation once it has been started. The worker who repeatedly changes his problem to chase his newest bright idea is usually ineffectual."

Clinicopathologic Conference

Tripler Army Hospital, APO 438, San Francisco, Calif.*

PROGRESSIVE DYSPNEA

Summary of Clinical History. A 34-year-old electrician and painter of Portuguese extraction was admitted to the hospital complaining of shortness of breath on exertion for one month.

Except for a marked susceptibility to colds, he said he had been in good health up to three months before admission, when he noted intermittent frontal headaches and some generalized muscle aches lasting for one month, and began to cough up small amounts of greenish sputum. One month before admission he noted dyspnea on exertion, which gradually increased in severity and was associated with some weight loss and fatigability. From onset of symptoms to admission, he had lost about 25 pounds. Two weeks before admission he first noted wheezing over the upper right side of his chest, as well as hoarseness and night sweats. He denied chest or abdominal pain, orthopnea, hemoptysis, chills, allergies, nausea, vomiting, jaundice, diarrhea, dysuria, or ankle edema. His past medical history revealed few of the usual acute childhood infections. He had gonorrhea at the age of 23 and a fractured foot 4 years later. He had been discharged from the Army 5 years before for psychoneurotic symptoms. He had had no medication except for routine treatment of his colds, no tobacco, and just an "occasional" beer.

There was no known exposure to tuberculosis or coccidioidomycosis. Six months before admission the patient had a routine chest roentgenogram taken which he was told was normal.

*Brig. Gen. John F. Bohlender, MC, USA, Commanding General. From the Laboratory Service, Col. Harold E. Shuey, MC, USA, Chief.

Physical Examination. The patient was a well-developed, chronically ill male in no acute distress. His temperature was 99.4°F; pulse, 80; respirations, 26; blood pressure, 126/84 mm Hg. Examination of the eyes, ears, nose, and throat was negative. Examination of the lungs revealed impairment to percussion over both bases anteriorly and posteriorly. The diaphragm moved freely. There was increased fremitus over the right lower chest. Fine inspiratory rales and intermittent wheezes were heard over both bases anteriorly and posteriorly. The heart, abdomen, and neurologic systems were negative on examination.

Laboratory Studies. Red blood cells numbered 3.6 million per μ l. The hemoglobin measured 10.2 g per 100 ml. There were 10,200 white blood cells per μ l with 64 per cent neutrophils, 30 per cent lymphocytes, and 4 per cent eosinophils. The erythrocyte sedimentation rate was 32 mm per hour, corrected (Wintrobe). Blood chemistry studies revealed the following: serum alkaline phosphatase, 10.4 Bodansky units; serum acid phosphatase, 1.5 King and Armstrong units; serum inorganic phosphorus, 4.4 mg per 100 ml; and serum calcium, 11.4 mg per 100 ml. The cephalin-cholesterol flocculation test was negative. Serologic examination of the serum revealed a negative Kahn test and no cold agglutinins. The urinalysis was negative, with no Bence-Jones protein. The sputum was very scanty, and no acid-fast bacilli were found on repeated smears and cultures. Gastric washings were also negative for acid-fast bacilli. Skin tests with coccidioidin and histoplasmin and a PPD (second strength) tuberculin test (on two occasions) were negative. A third tuberculin test was reported as eliciting a 3-plus reaction.

Chest roentgenograms taken on admission revealed "a feathery density in each lower lung field, most marked in the medial areas. The diaphragm is not involved. The heart is not enlarged. In areas the individual densities tend to become confluent, and in the right base the possibility of honeycombing is present. The upper lung fields show no evidence of disease." Films taken two months later on the second admission showed extensive coalescence of the densities so that they became homogenous, completely filling the lower two thirds of both lung fields from the hilum to the periphery. There was no apparent cardiac enlargement. A gastro-intestinal series and barium enema were nonrevealing.

Except for the roentgenographic findings described above, repeated laboratory tests showed little alteration during the course of the patient's illness. The serum inorganic phosphorus dropped to 3.4 mg per 100 ml. On the day before death, the white blood cell count rose to 39,800 per μ l with 92 per cent neutrophils. No pathogenic organisms were grown on repeated cultures.

Course in Hospital. On the first admission the patient remained in the hospital for 29 days, when he signed his own release. He received only symptomatic treatment. During this stay he developed no new physical findings or symptoms. At all times inspiratory rales could be heard over both bases. He ran a persistent low-grade fever, never above 100.4°F, and cough and sputum were almost entirely absent.

For a month the patient remained at home. Cough and dyspnea gradually increased; weight loss and fatigue became marked.

The patient was readmitted with severe dyspnea and marked cyanosis of the skin and mucous membranes. The temperature was 99.8°F; pulse, 120; respirations, 40; blood pressure, 124/80 mm Hg. Some clubbing of the fingers and toes was noted. The lungs showed slight dullness to percussion over both bases. Bronchovesicular breath sounds were equal throughout. There was good motion of the diaphragm. The heart was not apparently enlarged. The heart sounds were normal. The liver edge was palpable 4.0 cm below the right costal margin and was slightly tender. There were no palpably enlarged lymph nodes. The rest of the examination was essentially negative.

Since the nature of the patient's disease was not established, treatment was symptomatic. He was given penicillin and streptomycin sulfate. Despite high oxygen concentration by tent and mask, he showed marked cyanosis and dyspnea on the slightest exertion. He suffered severe aching pains across the front of the chest which were relieved by Demerol (brand of meperidine hydrochloride). No fluid was obtained at the time of a right thoracentesis attempted shortly before death. Death came quietly 73 days after the first admission.

DISCUSSION

Doctor Pitts:* This discussion deals with a 34-year-old male who developed a relentlessly progressive illness characterized by pulmonary insufficiency, with death 8½ months following a report of a normal chest x-ray, 5½ months after the onset of symptoms, and 3½ months subsequent to the onset of dyspnea. Associated symptoms consisted of a low-grade cough with constitutional manifestations of low-grade fever, considerable weight loss, and progressive debility. Objective findings revealed bilateral diffuse pulmonary involvement which appeared patchy and symmetrical without hilar adenopathy on the initial chest roentgenogram. Cyanosis at rest or on the slightest exertion, refractory to oxygen therapy during the latter part of his clinical course, suggested an alveolar-capillary block in the absence of evidence compatible with a venous-arterial shunt. Laboratory findings of mild anemia and an elevated serum globulin are considered nonspecific.

*Maj. Forrest W. Pitts, MC, USA, Department of Medicine.

The clinical manifestations were not those of acute or chronic parenchymal suppuration or bronchiectasis, and I believe these entities may be readily excluded without further discussion. Nor does this case fit the pattern of infection due to viral or rickettsial agents. Fungus diseases such as coccidioidomycosis, histoplasmosis, and blastomycosis may appear as diffuse bilateral progressive pulmonary disease, and negative skin tests are the rule rather than the exception in the disseminated and progressively fatal forms. At this point in the discussion, serologic studies do not discourage their elimination on the basis of negative cultures, lack of extra-pulmonary involvement, and subsequent death due to asphyxia. The tuberculin conversion is difficult to explain but this finding does not fulfill the usual significance attributed to it when an attempt is made to correlate it with other key features. The only plausible explanation for an individual to die of tuberculosis with extensive pulmonary involvement, repeatedly negative cultures for *Mycobacterium tuberculosis*, and clinical manifestations of an alveolar-capillary block is that associated with the miliary form of this disease; the latter is readily excluded by the appearance and distributions of the lesions on the chest roentgenogram (fig. 1).

Other causes to be considered are obscure diffuse bilateral pulmonary diseases, including pulmonary infiltration with eosinophilia, pneumoconiosis, lipoid pneumonia, lymphoma, uremia, and histiocytosis or lipogranulomatosis. These may be excluded because of the absence of expected associated findings and/or the less savage clinical course usually associated with these diseases.

Pulmonary adenomatosis (alveolar cell carcinoma, bronchiolar carcinoma) produces diffuse bilateral pulmonary lesions and an asphyxial type of death, but this condition usually runs a much more protracted course and is characterized by large quantities of clear mucoid sputum of low viscosity.

Diseases commonly associated with alveolar capillary block such as pulmonary arteriosclerosis, repeated multiple thromboses or embolization with infarctions of the pulmonary vascular bed, leukemia, sarcoidosis, beryllium granulomatosis, lymphangitic metastases, chemical pneumonia similar to that noted following inhalation of sulfur dioxide fumes, certain collagen diseases, and the type of diffuse interstitial pulmonary fibrosis described by Hamman and Rich¹ provide a more fruitful but difficult group to narrow down in the differential diagnosis. Cor pulmonale is common during the late stages of most of these entities, and I suspect the pathologist will find hypertrophy and dilatation of the right ventricle in this case, although little or nothing is stated in the protocol with reference to an electrocardiogram, cardiac fluoroscopy or evaluation of the cardiac silhouette in the lateral or oblique views, the presence or absence of distended neck veins, and dependent edema. Enlargement of the liver during the second hospitalization seems to be the only recorded manifestation of right ventricular failure.

Figure 1. Roentgenogram of the chest showing bilateral feathery densities in the medial portions of the lower lung fields.

The rapid downhill course, low-grade fever, x-ray appearance of the lesions, and lack of polycythemia lead me to exclude pulmonary arteriosclerosis. Repeated small thromboses or infarctions of the pulmonary vascular bed remain a possibility and cannot be excluded with certainty.

As an electrician, the patient may have been exposed to beryllium through contact with (now obsolete) broken fluorescent light tubes. This point in the history would be extremely important if positive, since all the features of his illness are compatible with such a diagnosis. Interestingly enough, a negative history would not exclude beryllium granulomatosis in the light of reported "neighborhood cases." However, lack of x-ray evidence of upper lobe involvement and absence

of a miliary type of lesion militates against this diagnosis as the most likely cause. Occupational exposure to sulfur dioxide gas as used in old refrigerators remains a less likely possibility and can be excluded reasonably well.

On the day prior to death, the white blood cell count was reported as 39,800 per μ l with 92 per cent neutrophils. I prefer to attribute this to an agonal leukemoid reaction rather than to myelogenous leukemia. It is difficult to conceive of a respiratory type of death from leukemia, particularly so in the absence of more severe anemia, retinal hemorrhages, and splenomegaly.

Could this be an unusual case of sarcoidosis? All of the key findings—diffuse bilateral pulmonary disease, low-grade cough and fever, alveolar capillary block, elevated serum globulin, and hepatomegaly from cor pulmonale and/or hepatic involvement—are in keeping with sarcoid. Occasionally sarcoid runs a progressive, fatal course, but for death to occur within such a brief span of time makes this possibility seem improbable. Lack of hilar or extrathoracic adenopathy and/or clear-cut involvement of other tissues or organ systems also rules heavily against sarcoid as the most likely diagnosis.

Carcinomatous lymphangitic metastases to the lung from an occult primary lesion such as that which may occur in the body or tail of the pancreas, the stomach, or the bronchus would account for all of the findings in the protocol and cannot be excluded from the final differential diagnosis with complete certainty. The x-ray appearance is not that of the "sunburst" pattern, and this factor lends considerable weight against this possibility.

Of the collagen diseases, scleroderma most frequently produces an alveolar-capillary type of block. The absence of cutaneous findings and other features readily leads one to exclude the possibility of scleroderma. Periarteritis nodosa may involve the medium-sized vessels of the lungs, subsequently producing an alveolar-capillary type of block and occasionally leading to destructive lesions in the lungs characterized by cavitation. Hypersensitivity angiitis characteristically involves the small vessels of both arteries and veins and runs a more acute course. It is not characterized by necrotizing granulomata. Hypersensitivity angiitis is usually associated with a generalized vasculitis and frequently terminates fatally from diffuse vascular involvement of uremia. A specific subtype of collagen disease was described in 1931 by Klinger³ and formulated by Wegener² in 1939. This is characterized by necrotizing granulomatous lesions in the upper air passages or in the lung, as well as renal changes manifested by necrosis and thrombosis of loops or lobes of the glomerular capillary tuft. In addition, there is generalized vasculitis. In reviewing the literature to 1954, Fahey⁴ found 22 cases of Wegener's granulomatosis in the literature and added seven cases of his own. Absence of both renal

involvement and diffuse organ or system involvement in this case tends to rule against a collagen type of disease such as hypersensitivity angitis or Wegener's granulomatosis.

In 1944 Hamman and Rich from Johns Hopkins described four cases of acute diffuse interstitial fibrosis of the lungs of undetermined cause observed from 1931 to 1943. All cases were characterized by cough, progressive dyspnea, cyanosis, and cor pulmonale. Autopsy revealed interstitial edema and hemorrhage with few leukocytes, and enlargement of the lining alveolar cells as well as necrosis of the alveolar and bronchiolar epithelium; a hyaline membrane was noted to line the alveoli, and bacteria were absent. None had vascular lesions similar to periarteritis nodosa. The most striking feature was a progressive, extensive, diffuse interstitial proliferation of fibrous tissue throughout all portions of both lung fields. The early stage was characterized by fibroblasts, and the late stages showed mature scar tissue. Survival times from the onset of symptoms varied from one to six months. The histories of Hamman and Rich's original cases are almost identical to that of the present protocol. Since the original description, a total of 27 cases had been recorded at the time Peabody and Peabody³ wrote an editorial on this condition in December 1954. Eighteen of the 27 cases have been reported since 1950.

The cause of the Hamman-Rich type of diffuse interstitial pulmonary fibrosis is unknown. Suggested causes have ranged from recurrent episodes of viral pneumonia, chemical irritants and hypersensitivity, to a disturbance of fibrinolysis. Pathologic changes similar to the Hamman-Rich type of involvement have been reported with five fatal cases of interstitial pneumonia which occurred while the patients were receiving prolonged Apresoline (brand of hydralazine hydrochloride) and hexamethonium therapy. Characteristically, all cases have been resistant to therapy. Initially, it was believed that duration of life was limited to weeks or months. There are now two patients who have survived three years and a third reported in 1949 to have survived 13 years after the onset of symptoms. Corticotropin and cortisone had been used empirically with equivocal effect. One striking case demonstrated a remission coincident with the onset of administration of these agents and followed by a severe exacerbation when they were discontinued. Most authorities agree that once steroids are started they should be continued for life.

Although it is difficult to pick out any single diagnosis with certainty, I believe the over-all features of this case best fit a diagnosis of the Hamman-Rich type of diffuse interstitial pulmonary fibrosis.

Doctor Bratenahl: * Before presenting the pathologic findings, I would like to know what further comments any of you would like to make regarding this case; in particular, any more guesses as to the most probable diagnosis. Would anyone care to comment further on the x-ray

*Comdr. Charles G. Bratenahl, MC, USN, Naval Medical Unit, Laboratory Service.

picture (fig. 1) in this case, correlating it with the history? Might anything significant be added to the x-ray description?

Doctor Blumley:* I have nothing to add to the description of the x-ray findings as given in the protocol. While beryllium poisoning has to be thought of, the patient having been an electrician, most cases of beryllium poisoning occur in factory workers making fluorescent bulbs. The roentgenographic finding in acute cases consists of widespread fine nodular infiltrations in the lung fields. With continued exposure this can go on to the chronic form of poisoning within three to four months, characterized by large granulomatous infiltrations in the lungs. Also related to his occupation as an electrician is the possibility of chemical pneumonitis by inhalation of hydrogen chloride, as electricians commonly use hydrochloric acid to clean electrical connections prior to soldering. Symptoms resulting from such exposure are headaches, substernal pains, dyspnea, and marked cyanosis—symptoms which this patient demonstrated.

Doctor Gangerosa:** Boeck's sarcoid is at times associated with pulmonary fibrosis and active tuberculosis terminally. The latter is manifest clinically by a reversion of the tuberculin skin test from negative to positive as seen in this case. This reversion has diagnostic import, I feel. Some believe that repeated skin testing with tuberculo-protein in a tuberculin-negative individual will induce a tuberculin reaction, but Raffel³ has shown that it is the waxy component, the lipid fraction of the tubercle bacillus, which is necessary in combination with tuberculo-protein to induce the tuberculin reaction. I, therefore, submit a diagnosis of Boeck's sarcoid with pulmonary fibrosis and active tuberculosis terminally.

Clinical diagnoses:

Undiagnosed condition manifested by bilateral pulmonary infiltrations suggestive of pulmonary adenomatosis

Dr. Pitts' diagnoses:

1. Hamman-Rich diffuse interstitial fibrosis of the lungs of undetermined cause
2. Terminal leukemoid reaction of the blood

Dr. Gangerosa's diagnoses:

1. Boeck's sarcoid, with pulmonary fibrosis
2. Active tuberculosis

PATHOLOGIC FINDINGS

Doctor Brotenohl: At autopsy the patient was a markedly emaciated 34-year-old Caucasian man. The skeletal muscles were atrophic, and there was marked lack of subcutaneous fat. Moderate clubbing of digits was noted. The heart weighed 350 grams, and the right ventricle was moderately dilated. There were 200 ml of pericardial fluid present. The heart valves were essentially normal.

*Maj. Nelson Blumley, MC, USA, Assistant Chief, Radiology Service.

**Capt. Eugene J. Gangerosa, MC, USA, Intern, Obstetrics and Gynecology Service.

The principal findings were confined to the lungs. The right weighed 1,710 grams, the left 1,600 grams. With sterile precautions, cultures of the right lung revealed *Pseudomonas aeruginosa*. There was no pleural effusion, but fresh fibrinous adhesions covered the pleura on both sides (fig. 2). Some fibrinous adhesions were noted at the left apex. The lungs appeared heavy and solid with no crepitation at all. They had a consistency almost like liver. Cut sections revealed almost homogeneous, light gray-white, rather solid lung tissue in all lobes, particularly solid in the lower lobes (fig. 3). There was no particular odor about the tissues. On slight pressure a thick, yellowish, opaque fluid oozed from the cut surface. This material was smooth and non-granular. On dropping the lung tissues into Formalin (brand of formaldehyde solution), it was noted that this material floated to the surface as oil droplets. Oil droplets were also noted in the bloody fluid remaining in the posterior thorax after removal of the lungs.

The bronchi were mostly filled with a thick, creamy material similar to that found on compressing the lungs. Some of this material was also found in the trachea. At the apex of the left lung, a red, soft area 5 cm in diameter was found containing semiliquid necrotic material and resembling a poorly walled-off abscess. Although in general the pulmonary lobular markings and other architecture of the lungs were well preserved, no definitely aerated tissue was demonstrable on gross examination. The tracheobronchial and paratracheal lymph nodes were enlarged up to 3.0 cm in diameter (fig. 2). On cut section, they appeared homogeneous and gray-white.

Microscopic sections of the lungs showed a heavy, acellular, fibrinous exudate on the pleura associated with some congestion. Innumerable large macrophages with foamy cytoplasm were found in the septae as well as filling many of the alveoli (fig. 4). Numerous young fibroblasts were also noted in the alveolar septae and proliferating within the alveoli (fig. 5). The alveoli in many areas had a cuboidal epithelial-cell type of lining (fig. 6). The lungs appeared very dense on all sections. Section from the left upper lobe in the area grossly suggesting an abscess showed considerable fibrosis but no distinct abscess. On hematoxylin-eosin sections, many of the alveoli were filled with a basophilic-staining, granular, amorphous precipitate in which were numerous small and large vacuoles (fig. 6). Frozen sections of lung stained with Sudan IV showed intensely red-staining oil droplets in these vacuoles and within the macrophages in the alveoli and alveolar septae. This fatty material did not stain with osmic acid and was not doubly refractile. Occasional conglomerate masses of reticulo-endothelial cells were noted in the alveoli, vaguely simulating giant cells; however, no true multinucleated foreign body giant cells were found. Sections of peribronchial lymph nodes showed the sinusoids crowded with fat-filled macrophages, which stained positively with Sudan IV and negatively with osmic acid.

Figure 2. Medial aspect of left lung showing fibrinous pleural reaction and enlarged gray-white hilar lymph nodes. Figure 3. Left lung in cut section showing uniform gray-white consolidation throughout.

Figure 4. High power photomicrograph of lung showing vacuolated macrophages in alveoli and thickened alveolar walls. ($\times 400$)

Figure 5. Photomicrograph of section of lung showing diffuse fibrosis of alveolar walls with lipophages and proliferating fibroblast tissue in the alveoli. ($\times 80$)

Figure 6. Photomicrograph of lung showing fibrous thickening of alveolar walls with large numbers of lipophages in the walls and alveoli, basophilic material and large and small vacuoles, and dissolved oil droplets in the alveoli. Some of the alveoli are lined by cuboidal epithelium probably derived from the bronchioles. ($\times 80$)

Shortly before this patient's death it was learned that, for a long unknown period of time before his first hospitalization, he had used large quantities of oily nose drops and possibly an oil-containing nose spray for his repeated head colds. He denied using any of this material after his initial admission and up to the time of his death.

The staining reaction of the fatty material found within the lungs in large quantities, positive for Sudan IV and negative for osmic acid, is consistent with mineral oil (liquid petrolatum) in contrast with vegetable and animal oils.⁷ Some caution in strict interpretation is necessary as the Sudan IV stain is not entirely specific for mineral oil.⁸ The pathologic findings of diffuse pulmonary fibrosis associated with large numbers of lipophages in the alveoli and interalveolar septi and the general lack of specific foreign body or inflammatory reaction are consistent with findings reported in previous cases of lipoid pneumonia due to mineral oil.

Vegetable oils, such as Lipiodol (brand of iodized poppy seed oil), sesame oil, or olive oil, usually result in little reaction of the lung tissues. These oils are slowly absorbed with little residual fibrosis. Animal oils, such as cod liver oil or halibut oil, usually cause a much

more acute reaction associated with marked fibrosis and rather striking giant cell formation in a few days. The latter type of lipoid pneumonia occurs mostly in infants, and there is usually a history of attempting to force a sick child to swallow cod liver oil against his will, possibly by holding his nose. If his reflexes are weak from illness, he tends to gag and aspirate considerable oily material. Although the reaction is quite severe, it is frequently self-limited.

Lipoid pneumonia resulting from liquid petrolatum is more often found in adults, usually elderly, and as a result of using oily nose drops. Characteristic pathologic findings consist of lipophages in the alveoli and alveolar walls surrounded by a fibrous reticulum, filling much of the air spaces and tending to concentrate in the bases of the lungs posteriorly. The elderly patient has usually employed the oily nose drops or sprays over a long period of time. When x-rays show a picture suggesting a low-grade bronchopneumonia in the bases that does not resolve and that is associated with almost no symptoms, the possibility of lipoid pneumonia should be considered. Death usually results from a secondary infection, and the diagnosis is rarely made before death. The sputum may occasionally show lipophages, but this finding is not very helpful since they may be found in various other conditions. The lungs usually appear yellowish and solid, and usually there is an absence of pleural exudate or adhesions. The fibrinous pleural exudate present in this case and the high globulin and alkaline phosphatase values reported here are puzzling features not completely explained. Are there any other questions?

Doctor Pulaski:* I believe some of you may be interested in a case very similar to the one presented in this Clinicopathologic Conference. It was reported by Stanley⁹ in 1947. This was a case of pyocyaneus pneumonitis associated with lipoid pneumonia in a 73-year-old Caucasian man. He had suffered with recurrent sinusitis over a period of 16 years, and it was believed that the lipoid pneumonia resulted from his use of oily nose drops. In his case the pyocyaneus pneumonitis was much more extensive and the lipoid pneumonitis much less so than in our present case. He died on the sixth day after admission. Since primary pneumonitis due to *Bacillus pyocyaneus* is a relatively rare occurrence, the interesting thought occurs as to a possible relationship between the lipoid pneumonia and pyocyaneus pneumonitis.

Pathologic diagnoses:

1. Lipoid pneumonia, secondary to the use of oily nose drops
2. Terminal pneumonitis, due to *Pseudomonas aeruginosa*

*Lt. Col. Edwin J. Pulaski, MC, USA, Assistant Chief, Department of Surgery.

ON DROWNING

"If a victim has flooded his lungs with fresh water and yet has been successfully resuscitated then it would appear certain that he would be suffering from plethora, haemodilution, electrolyte disturbance, and pulmonary oedema. Further, he would be in danger of severe renal damage from the presence of freely circulating haemoglobin. Substitution bleeding with electrolyte correction, treatment for acute kidney damage, and oxygen therapy for pulmonary oedema and lung flooding would seem to be indicated. Hypotonic saline and oxygen therapy may be of help in those saved from salt-water drowning. The almost complete absence of any clinical reports of patients requiring and receiving such treatment in the vast medical literature of today can hardly be due to a deliberate silence on this subject, and it is difficult to avoid the sinister interpretation that such syndromes probably do not exist and that the aspiration of any marked quantity of water into the lungs is fatal."

MILITARY OTOTOLOGY AND AVIATION MEDICINE

FRANK A. PERRI, *Lieutenant Colonel, USAF (MC)*

DURING 15 years as a physician with the Air Force, I have been impressed by the number of medical officers who are not fully aware of the important and close association of ear disease with military aviation medicine. Perhaps this is because many otolaryngologists are not flight surgeons and many flight surgeons have not made a special study of otolaryngology.

Both groups are faced repeatedly with otologic conditions that require immediate therapy in order to maintain trained crew personnel at peak performance. Many an otologic problem even seems to mean the end of the flying career of a highly proficient pilot, when in reality it is an easily repairable defect that should be only temporarily incapacitating. Conversely, there are minor conditions which can become irreversible and may well end a flying career if proper precautionary steps are not initiated immediately. Into another class fall the seemingly harmless diseases of the ears, nose, and throat which require that immediate steps be taken to remove crew members from flying status for the safety of all concerned.

BAROTITIS MEDIA

Barotitis media (aero-otitis media) is an acute inflammation of the mucosa of the middle ear caused by trauma to the mucosa from inequality of pressure in the middle ear and external auditory canal. If left untreated, the disease may progress to serious complications. Because of negative pressure in the middle ear, the blood vessels undergo rapid dilatation. Failure to ventilate the middle ear at this stage further results in an intense congestion of the tympanic membrane and an actual ecchymosis of the membrane and middle ear cavity. The membrane often ruptures when the pressure in the middle ear is rapidly reduced while the eustachian tube is closed. Prolonged negative pressure in the middle ear produces transudation of a yellow serosanguineous fluid into the middle ear cavity and the mastoid air cells. This transudate then becomes infected, leading in various cases to acute suppurative otitis media, acute or chronic suppurative or nonsuppurative mastoiditis, acute or chronic eustachian salpingitis, or destruction of the tympanic membrane with loss of hearing in the involved

From U. S. Air Force Hospital, Sampson Air Force Base, Geneva, N. Y. Col. Perri is now assigned to U. S. Air Force Hospital, Chanute Air Force Base, Rantoul, Ill.

ear. In clinical practice, all of these conditions have been seen as a result of untreated or insufficiently treated barotitis media.

The prevention of complications and the maintenance of crew personnel in constant flying readiness depends upon immediate and proper therapy. Crew personnel should be instructed in the early recognition of this condition, and should adopt prophylactic measures, as follows:

1. In the presence of acute inflammatory conditions of the upper respiratory tract, no matter how mild, crew personnel should not be permitted to fly.

2. When descending from high altitudes, the oxygen mask should be removed at altitudes of less than 10,000 feet. Personnel who have been breathing pure oxygen at high altitudes for a considerable period may develop ear distress from two to six hours after descent, particularly if oxygen is breathed until ground level is reached. This is caused by absorption of oxygen from the middle ear in the presence of eustachian tube obstruction.¹

3. Upon the onset of barotitis media during flight, ascent to a higher altitude should be made immediately, followed by a slow descent while attempting the Valsalva maneuver.

4. If the condition persists, crew personnel should report to the unit surgeon immediately after landing.

Diagnosis. When the condition has progressed until the middle ear is filled with fluid, diagnosis and therapy become major problems. The diagnosis can be made upon the history, by inspection of the tympanic membrane, and by insufflation of the middle ear if required. In the history, the patient will usually mention one or all of the following symptoms: loss of hearing or muffled hearing, fullness in affected ear, "water in ear," and tinnitus. The examiner usually sees a slight retraction and yellowish tinting of the tympanic membrane, with redness at the periphery of the membrane and along the handle of the malleus. A fluid level and/or bubbles of air may appear in the middle ear cavity. If the whole middle ear is filled with transudate, no fluid level will be seen and the middle ear must be insufflated in order to view air bubbles and establish the diagnosis.

Therapy. When transudate is not present, therapy consists of reducing congestion and pressure differences between the middle ear and the atmosphere. The first is done by applying a copious spray of a one-quarter of one per cent solution of Neo-Synephrine Hydrochloride (brand of phenylephrine hydrochloride) to the mucosa of each nasal fossa. A cotton-tipped metal applicator soaked in a 5 per cent solution of cocaine hydrochloride is applied to the orifice of the eustachian tube on the affected side for five minutes.

A eustachian tube cannula is then placed at the orifice of the tube, and air is introduced at a pressure of from 3 to 4 pounds. The Toynbee diagnostic tube that connects the ear of the patient to the ear of the flight surgeon indicates the instant that air reaches the middle ear, restoring its normal physiology.

When transudate is present, it must first be aspirated. A 3-inch-long, 22-gauge spinal needle with a short bevel, attached to a tuberculin syringe, is introduced into the middle ear through the most inferior posterior portion of the tympanic membrane, and the fluid is aspirated slowly. No anesthesia is required, as very little discomfort is experienced. The nasal mucosa is then constricted, the orifice of the eustachian tube cocaineized, and the middle ear insufflated as previously described, in order to remove any remaining transudate. This therapeutic procedure reduces the period of convalescence from 21 to 5 days. The perforation of the tympanic membrane is completely healed within 48 hours, and seldom is there a recurrence of the transudate after the pressure on both sides of the tympanic membrane has been equalized.¹

TRAUMATIC CENTRAL PERFORATIONS OF TYMPANIC MEMBRANE

Central perforations of the tympanic membrane are distinguished from peripheral by the fact that the whole rim of the perforation is within the tissue substance of the membrane, inferior to Shrapnell's membrane, and not in contact with the bony annulus tympanicus. This type of perforation occurs in crew members during rapid descent in flight or in altitude chambers, and during and after acute infections of the nose and throat.

That traumatic central perforations do persist and often resist nature's efforts to heal them is all too manifest in the practice of clinical otology, but with adequate therapy, this need not occur. There also is no dispute that certain central perforations do produce a loss of hearing and subject the middle ear to a chronic suppurative infection followed by more severe complications; however, Adams² reported a series of cases in which there was successful healing of these perforations along with eventual return of hearing in the affected ear as proved by audiometric study.

If the examining physician finds that a central perforation of the tympanic membrane has not initiated its own healing process within 48 hours following trauma, the flight surgeon should then take the proper measures to close the perforation.

Therapy. The following therapy, which has proved successful in a number of our cases, is performed on an outpatient basis while the crew member is on a nonflying duty status:

After bilateral audiometric study, the whole rim of the perforation, plus a small portion of the outer surface adjacent to the rim, is touched with a small amount of very compact absorbent cotton that has been placed on the end of a copper applicator and moistened at the tip with 50 per cent trichloroacetic acid. This is repeated twice weekly, depending upon the membrane response, for at least eight weeks. In many instances there will be a rapid response to therapy, in which case the strength of the trichloroacetic acid is decreased and the solution applied only once each week. A second audiometric study is made after the perforation has healed.

BAROSINUSITIS

The paranasal sinuses present a condition in flight similar to that of the middle ear, except that their orifices, when not closed by mucosal congestion, are fully patent and rigid at all times. Mucosal congestion will prevent an exchange of air and pressure between the paranasal sinuses and nasal fossa during descent from altitude, with the result that pain in a sinus will be experienced because of the pressure inequality. Transudation and secondary infection may follow.

The flight surgeon can alleviate the discomfort and pain of barosinusitis by inserting a pledget of absorbent cotton soaked in 0.25 per cent Neo-Synephrine Hydrochloride in and around the middle meatus. The pledget is left in place for five minutes. If the condition is not relieved after this period, the procedure is repeated. After the second application, it will be noted that the nasal mucosa has reached maximum vasoconstriction, both nasal airways are patent, and the pain and discomfort have disappeared because the sinal pressure is atmospheric. A roentgenographic study is made in order to rule out pathologic conditions of the sinuses. The patient is then placed on a solution of 0.25 per cent Neo-Synephrine Hydrochloride solution and instructed to use 10 drops of the solution in each nostril while in the head-low (Proetz) position.

SUMMARY

The important role of ear disease in aviation medicine has not been sufficiently emphasized. Proper care and disposition of many aviation patients depend on thorough knowledge of diagnostic criteria, treatment, and prognosis of ear disorders.

Barotitis media may be diagnosed from the history, from inspection of the tympanic membrane, and by insufflation of the middle ear if necessary. If there is no transudate in the middle ear, therapy consists of reducing congestion at the nasal end of the eustachian tube and equalizing the pressure on the two sides of the tympanic membrane. If a transudate is present, these measures must be preceded by aspiration. If inadequately treated, barotitis may result in permanent hearing loss.

Traumatic central perforation of the tympanic membrane in my experience has healed most rapidly if treated with topical applications of 50 per cent trichloroacetic acid.

The paranasal sinuses may react to pressure changes in a manner similar to the middle ear, if their orifices are blocked by mucosal congestion. Barosinusitis responds well to treatment with topical vasoconstrictors.

These three seemingly minor otolaryngologic conditions may attain extreme importance when they occur in flying personnel. When not treated promptly and adequately, they cause the loss of highly trained personnel.

THE PHYSICIAN AS AN INDIVIDUAL

"It is axiomatic that treatment must be individual and will vary from patient to patient. But what is true of the patient is also true of the doctor. The resourceful physician presumably will not attempt to follow unquestioningly any fixed school of teaching. Medical education does not standardize the personality of the doctor. Each will and should have his own manner of dealing with patients, developing a flexible psychotherapeutic technique best suited to his own nature."

Journal*, p. 256, Feb. 15, 1956

DENTAL EXAMINATIONS OF 8,139 ARMY RECRUITS

Preliminary Report

ROBERT W. HOBSON, *Lieutenant Colonel, DC, USA*

PERIODICALLY, members of the U. S. Army Dental Corps have been asked by various organizations for information concerning the dental status of Army recruits. Prior to this study no compilation of information was available on which to base an adequate reply.

METHOD

Examinations were conducted in all of the six Army Areas during the months of April and May 1955. Every third enlisted man within the category of recruit or separatee who reported to the dental clinic was examined. By distributing the examination points throughout the United States and by examining every third individual within the specified time, sufficient randomness was obtained to give the results validity.

For the purpose of this study, a recruit was defined as "an inducted or enlisted man without prior military service." A separatee was defined as "an enlisted man who has completed not less than 20 and not more than 24 months of service."

Although the examination form used (fig. 1) admittedly has its limitations, it was considered desirable to employ a form from which all information could be transcribed to a single IBM punch card. The fact that spaces for recording are limited on such a card imposed a limitation on the number of questions that could be answered. Under part 8b, the clinical examination was to include bite-wing roentgenograms. In part 12 (prosthetics), the extractions needed as well as missing teeth and unserviceable dentures were to be reflected under the column headed "needed." The numbers in the columns in this part were for coding purposes only, and were to be disregarded by the examining officer.

This preliminary report includes only the recruits examined. No analysis has been made of the geographic distribution of this

group of individuals, or of their dental classification. The information derived from these two parts of the study will be reported at a later date.

Figure 1. Examination form for dental evaluation.

RESULTS

Of the 8,139 recruits examined (table 1), 7,889, or 97 per cent, were in the group aged 17 through 26 years. It is this age group that is of most interest, because selective service at present

draws mainly from the group aged 18 through 26. From table 1 it can be determined that the 7,889 recruits aged 17 to 26 years required 38,137 restorations involving 57,267 surfaces, or an average per man of 4.8 restorations involving 7.3 surfaces.

TABLE 1. *Restorations needed by 8,139 recruits*

Age	Number of recruits	Number of restorations needed	Number of surfaces	Average number of restorations needed	Average number of surfaces involved
16	4	20	24	5	6
17	879	5,446	7,642	6.20	10.15
18	1,410	7,119	10,688	5.05	7.25
19	1,604	7,022	11,229	4.88	7.64
20	1,442	7,225	11,118	5.01	7.75

Total	8,139	39,017	58,543	4.8	7.2

In the assessment of defective fillings (table 2), the examining officer was cautioned to count only those restorations where caries had reoccurred or the material had broken, badly washed, or loosened for some unknown cause. Even with these criteria, it was found that approximately one out of four recruits needed a defective restoration replaced.

The impossibility of rehabilitating patients dentally, with the present dentist-troop ratio, can readily be seen from table 3, which shows that for every four recruits, one bridge is needed.

The tremendous amount of time required for this type of treatment precludes its being rendered except when it is needed in the anterior portion of the mouth.

TABLE 2. *Defective fillings present on examination*

Total	8,139	2,102

The number of missing teeth (table 4) per recruit is 3.93, and the number of extractions needed averages 0.8 per individual. This does not take into consideration extractions that may be required when operative procedures are attempted or when prosthetic work is started.

A reflection of this total (4.73 missing teeth, when extractions are completed) can be seen in table 5, which lists the dentures needed. The results of this examination show that for every 100 recruits, 19 dentures of all types are required.

Table 6 reveals that 22 per cent of the recruits were in need of periodontal treatment of some degree, and that 45 per cent were in need of a prophylaxis.

DISCUSSION

A review of the literature¹⁻⁵ along with personal correspondence was made in an attempt to arrive at the probable number of new carious lesions per year in the recruits examined. The first large scale compilation that could be found was done by Hollan and Dunning,² who reported an annual increment of 1.75 new carious surfaces per person. Klein⁴ found that in the young adult or college freshman age group, an annual increment of about 1.5 could be expected. Arnold, Dean, and Singleton⁷ found an annual increment of 2.2 new carious surfaces per year. Examination of a group of freshman college students in Des Moines, Io

In view of the preceding findings, I believe that 1.5 is a conservative estimate of the annual new caries rate for recruits in the Army. This would mean a total of 3 new lesions during the 2-year obligated period. Added to the average number of restorations needed on induction, it can be seen that the average young man of draft age, during his 2-year period in the Army, would require the insertion of 7.6 restorations if he were to be discharged in a caries-free condition.

revealed 2.2 new carious lesions per person during the first year.* In the student body at Northwestern University Dental School, the annual rate established over a period of years with radiographic examinations was 1.2 new carious lesions per year.*

SUMMARY

An examination of 8,139 recruits from all six Army Areas was conducted in order to determine the dental status of this group of young men. During a two-month period every third recruit reporting to the dental clinic was examined, and the results were recorded on a standard form.

For the average recruit, 4.8 restorations involving 7.2 surfaces were needed. One out of every four individuals needed a defective filling replaced, and one out of every four was in need of a bridge. The average recruit was missing 3.93 teeth with 0.8 extractions indicated. This did not include extractions needed for the construction of prosthetic appliances or where it was found impossible to render restorative treatment. For each 100 recruits, 19 dentures of all types were needed. Twenty-two per cent of all

patients examined had some degree of periodontal involvement, and 45 per cent were in need of a prophylaxis.

A review of the literature indicates that a caries expectant rate for each individual of 1.5 new lesions per year would be a conservative estimate. Coupled with the need for dental treatment observed in the average recruit, this means that during his two-year period in the Army, the average young man of draft age would require the insertion of a total of 7.6 restorations to discharge him in a caries-free condition.

"Nevertheless, in most cases of furring of the tongue the cause of the furring is probably to be found in one of three conditions: local infection, a dry mouth, or the irritant effect of tobacco smoke. Local infection may come from the mouth itself (as in stomatitis), or from the nose or throat (as in tonsillitis, colds, and sinusitis), or from the lungs (as in bronchitis and pneumonia). Dehydration of the mouth may result from a general state of dehydration, or from the dry mouth of a fever, or from blocked nose, and smoking presumably acts by the direct irritant action of tobacco smoke on the tongue."

MARITAL ADJUSTMENT PROBLEMS IN AN OVERSEAS THEATER

Psychiatric Implications

JOHN W. BURKETT, *Major, MC, USA*

THOSE who deal with emotional problems often need to be reminded that psychiatric patients cannot be considered as isolated cases or disease entities. They must be evaluated and understood in terms of their interpersonal relationships and of how their emotional difficulties affect not only themselves but others. To represent them as decompensations without reference to their current interpersonal relationships is of limited value in practical management.

Meaningful or positive interpersonal relationships such as close friendships, family ties, and good marital bonds constitute the foundation of mental health. They promote individual security and enable individuals to form group identities. Such factors are of recognized value in helping to sustain the soldier or officer in peace or combat. An impairment or paucity of such meaningful interpersonal relationships may result in loss of emotional support and consequent neurotic attempts to solve emotional problems.

The family life of both enlisted and officer personnel is often of primary importance in determining emotional adjustment. A careful evaluation of family life may reveal the dynamics of an otherwise obscure psychiatric disorder. It may be useful or even indispensable to interview and evaluate the wife and sometimes the children of the serviceman or officer with psychiatric symptoms. Conversely, when wives or children come to the psychiatrist for consultation, an evaluation of the emotional status of the husband is frequently indicated. The value of taking special note of current interpersonal relationships is well recognized by psychiatrists, but may be overlooked by other medical officers. Failure to take the patient's total current behavior into consideration often results in an inaccurate diagnosis and consequent improper management of the case.

From Army Medical Service School, Brooke Army Medical Center, Fort Sam Houston, Tex. Dr. Burkett is now at Veterans Administration Hospital, Sepulveda, Calif.

This article emphasizes the need for taking all interpersonal relations of the patient into consideration, with special emphasis on marital adjustment, and points out the importance of this concept in an overseas theater, where marital problems appear to be more frequent than in the United States. It is believed that there was an actual increase in the more serious types of marital difficulties among military personnel in overseas theaters during the past few years, and the absence of the usual civilian physicians and ministers, to whom people with marital problems often turn, tended to increase the number of such cases encountered.

DISRUPTIVE FACTORS

Overseas service presents unique factors which one would expect to increase general family problems, in particular marital difficulties. The most obvious of these is the usually long separation of the husband from the family. The necessity for the entire family to adjust to a foreign culture that is obviously different in language and customs and subtly different in attitudes and philosophy also plays a causative role. The anxieties of being in a potential combat zone tend to be displaced onto other situations and to exercise an adverse effect on family life. Children are faced with the emotional stresses incident to changing schools and forming new friendships when they arrive overseas. In the younger children the absence of the father for a significant period of time almost always causes some emotional problems. The presence of relatively large numbers of unmarried women with a low standard of living increases the possibility of marital infidelity with its consequent detrimental effect on family life.

Many of the officers and noncommissioned officers who were sent overseas during 1951 and 1952 had been recalled from the reserves and were faced with their second major disruption of family life within a few years. The availability of domestic help tended in many instances to decrease positive activity and to create leisure time that housewives were not equipped to use constructively. Family life for the husband in the combat unit was even more difficult. His intensive field training resulted in frequent and prolonged separations from his family even after they arrived overseas.

It is probable that all these and many other factors were operative in creating unique problems which in many instances resulted in marital tensions. This does not imply that severe marital difficulties were universal, for in most instances these problems were met realistically and an adequate adjustment made.

LEGAL COMPLICATIONS

In cases of definite marital discord, legal and administrative red tape created additional problems. Legal separation was impossible, and return of the family to the United States might take

many months of endeavor. Temporary separation, which at times may help marital problems, was almost impossible. In a number of instances husbands who frankly admitted having girl friends continued to live with their families. This created an obviously impossible situation for the wife. She was put in the position of having either to report this situation to her husband's commanding officer or to attempt to ignore his conduct. Bringing the husband's actions to the attention of his commanding officer would probably result in disciplinary action in the form of a fine and thus result in a financial loss to the family. Attempting to ignore his conduct was rarely a satisfactory solution. The husband, if a noncommissioned officer, was usually reluctant to move out of his family quarters because it would result in forfeiture of his coveted permanent pass and seriously interfere with his romance.

ANALYSIS OF CASES

The frequency of marital adjustment problems is reflected in this study of 173 dependent wives who were seen for psychiatric evaluation at an Army hospital in the period June 1953 to June 1954. Of these, 31 had serious marital problems in which at least one partner contemplated divorce, the wife contemplated return to the United States, or the husband was openly unfaithful. None of these 31 wives were psychotic, but all gave indications of previous emotional instability, neurotic symptoms, or severe dependency needs.

Of the dependent wives evaluated there was a higher ratio of hospitalizations (18 out of 31) than normally occurs in psychiatric practice. This is probably due to the fact that outpatients were usually from the local area served by the hospital, while most of the hospitalized patients were transferred from other hospitals. Many of these patients had been treated unsuccessfully with various medications; often they had not confided in the medical officer who first saw them, nor had he asked them about their general life adjustment.

CASE REPORTS

The following cases illustrate the effects of severe marital problems.

Case 1. The 41-year-old wife of a Sergeant was admitted to the closed psychiatric ward because of sudden and complete amnesia. She stated that she did not remember her identity or any of her past life, and did not recognize her husband. Her husband stated that just prior to the onset of her symptoms she "became cold as ice and shook all over." When the husband was interviewed, he was at first guarded and stated that nothing unusual had happened recently and that he could think of no emotional disturbances in the home. With encouragement, however, he disclosed that two days prior to the onset of his wife's amnesia he had told her he wanted a divorce in order to marry a European girl. He

had previously hinted at his dissatisfaction with their marriage, and had made little effort to conceal his interest in the other woman. The patient had refused to discuss the problem with him.

During the interview, the husband frankly stated that he had fallen in love with the other woman and had no intention of trying to continue his marriage. He did, however, express some guilt in relation to his wife's illness and said that he would take no further action until she was well. Questioning revealed that he was influenced by the other woman's ability to make him feel important.

The patient's past history revealed a lifelong pattern of passivity, dependency, marked feelings of inferiority, and severe sexual conflicts. Although she had had no previous psychiatric hospitalizations, she had experienced a period of amnesia lasting several hours at the port of embarkation just prior to going overseas. It was subsequently learned that she had been uncertain about joining her husband because of his apparent indifference to her joining him, as reflected in his letters. She had previously been married, as had her present husband, and had three children by her first marriage. She married her present husband two years prior to his going overseas, largely because of economic insecurity.

She had complete amnesia and perplexity on admission to the hospital, but recalled all events following her entry. There was no indication of psychotic behavior or thought content.

During the first three days of her hospitalization she gradually recalled a few things about herself, among them her first marriage but not her present one. She also recalled some details of her early childhood. For several days she made no further progress despite daily psychotherapeutic interviews and strong suggestion. During intravenous administration of Amytal Sodium (brand of amobarbital sodium) she was able to recall all the details of her present marriage. This was accompanied by considerable emotional display. Following the interview she was tearful, depressed, and anxious. As she responded to psychotherapy, she was discharged and followed as an outpatient. She eventually was able to face her marital problem without recourse to neurotic symptoms.

Comment. This patient was a very dependent person who was unable to bear the thought that her husband wanted to divorce her, because it threatened her self-esteem and created feelings of helplessness. Her symptom of amnesia was clearly a rather poor defense against the anxiety that the conscious realization of her problem would create. Although the amnesia cleared after the administration of Amytal Sodium, it was followed by anxiety and depression.

Case 2. The 30-year-old wife of a Captain brought her 7-year-old son to the psychiatric clinic, stating that he complained of abdominal pain and was nauseated and irritable. He had been referred from the pediatric clinic after thorough evaluation failed to reveal any physical

cause for his complaints. He had been given various medications without improvement. Following her description of the child's behavior and symptoms she said that she herself had lost 31 pounds. She went on to say that the child complained most when she was upset and that she felt maybe she was more in need of help than the child was. She then suddenly stated that she was very upset lately because her husband was having an affair with a girl. Her husband had told her that he planned to retire overseas and live with the girl. She had been married eight years and believed that prior to her arrival a few months ago she had had no major marital difficulties.

She appeared to be a rather insecure, passive woman, but her previous emotional adjustment had been fairly good. She gave a history of severe tension-type headaches for many years. During the interview she cried a great deal and said that she did not want to leave her husband for fear of losing his financial support and of being unable to provide for herself and her child. Her husband had stated openly and definitely that he intended to continue his affair with the girl; however, he was reluctant to apply for his wife's return to the United States because he felt that it might adversely affect his Army career.

The child was pale and timid but not severely disturbed. It was clear that he was well aware of his parent's marital difficulties and was concerned about them. The mother was seen as an outpatient several more times and finally was able to go to her husband's commanding officer and discuss the entire problem with him. The child was not seen again, but the mother reported that he had become asymptomatic. The commanding officer said she could not go back to the United States without her husband's consent, but he impressed the husband with his duty to his family and the unreality of his present attitude toward his wife, and indicated that a modification of his attitude was desirable.

Comment. In this case, what appeared to be a pediatric problem was only part of a generally disturbed family situation. The mother was a very dependent person and totally unable to insist that her husband discontinue his affair with the girl. She clung to the fantasy that her marriage was a success and the present affair more the fault of the girl than of the husband.

Case 3. The 45-year-old wife of a Captain with 17 years' service was admitted to the psychiatric section after an apparent suicide attempt with a sedative. Her husband had found her unconscious on the steps of their home on the evening of admission. According to her husband, her behavior that day had not been unusual. She had served his dinner in the usual manner and then said that she was going for a walk with the dog. Just before leaving she took eight Seconal (brand of secobarbital sodium) capsules, which she previously had been given at another medical installation because of insomnia.

Interview with the husband revealed that during their 13 years of marriage there was little real affection between them, and that he had never considered the marriage a great success. He had, however, con-

had previously hinted at his dissatisfaction with their marriage, and had made little effort to conceal his interest in the other woman. The patient had refused to discuss the problem with him.

During the interview, the husband frankly stated that he had fallen in love with the other woman and had no intention of trying to continue his marriage. He did, however, express some guilt in relation to his wife's illness and said that he would take no further action until she was well. Questioning revealed that he was influenced by the other woman's ability to make him feel important.

The patient's past history revealed a lifelong pattern of passivity, dependency, marked feelings of inferiority, and severe sexual conflicts. Although she had had no previous psychiatric hospitalizations, she had experienced a period of amnesia lasting several hours at the port of embarkation just prior to going overseas. It was subsequently learned that she had been uncertain about joining her husband because of his apparent indifference to her joining him, as reflected in his letters. She had previously been married, as had her present husband, and had three children by her first marriage. She married her present husband two years prior to his going overseas, largely because of economic insecurity.

She had complete amnesia and perplexity on admission to the hospital, but recalled all events following her entry. There was no indication of psychotic behavior or thought content.

During the first three days of her hospitalization she gradually recalled a few things about herself, among them her first marriage but not her present one. She also recalled some details of her early childhood. For several days she made no further progress despite daily psychotherapeutic interviews and strong suggestion. During intravenous administration of Amytal Sodium (brand of amobarbital sodium) she was able to recall all the details of her present marriage. This was accompanied by considerable emotional display. Following the interview she was tearful, depressed, and anxious. As she responded to psychotherapy, she was discharged and followed as an outpatient. She eventually was able to face her marital problem without recourse to neurotic symptoms.

Comment. This patient was a very dependent person who was unable to bear the thought that her husband wanted to divorce her, because it threatened her self-esteem and created feelings of helplessness. Her symptom of amnesia was clearly a rather poor defense against the anxiety that the conscious realization of her problem would create. Although the amnesia cleared after the administration of Amytal Sodium, it was followed by anxiety and depression.

Case 2. The 30-year-old wife of a Captain brought her 7-year-old son to the psychiatric clinic, stating that he complained of abdominal pain and was nauseated and irritable. He had been referred from the pediatric clinic after thorough evaluation failed to reveal any physical

cause for his complaints. He had been given various medications without improvement. Following her description of the child's behavior and symptoms she said that she herself had lost 31 pounds. She went on to say that the child complained most when she was upset and that she felt maybe she was more in need of help than the child was. She then suddenly stated that she was very upset lately because her husband was having an affair with a girl. Her husband had told her that he planned to retire overseas and live with the girl. She had been married eight years and believed that prior to her arrival a few months ago she had had no major marital difficulties.

She appeared to be a rather insecure, passive woman, but her previous emotional adjustment had been fairly good. She gave a history of severe tension-type headaches for many years. During the interview she cried a great deal and said that she did not want to leave her husband for fear of losing his financial support and of being unable to provide for herself and her child. Her husband had stated openly and definitely that he intended to continue his affair with the girl; however, he was reluctant to apply for his wife's return to the United States because he felt that it might adversely affect his Army career.

The child was pale and timid but not severely disturbed. It was clear that he was well aware of his parent's marital difficulties and was concerned about them. The mother was seen as an outpatient several more times and finally was able to go to her husband's commanding officer and discuss the entire problem with him. The child was not seen again, but the mother reported that he had become asymptomatic. The commanding officer said she could not go back to the United States without her husband's consent, but he impressed the husband with his duty to his family and the unreality of his present attitude toward his wife, and indicated that a modification of his attitude was desirable.

Comment. In this case, what appeared to be a pediatric problem was only part of a generally disturbed family situation. The mother was a very dependent person and totally unable to insist that her husband discontinue his affair with the girl. She clung to the fantasy that her marriage was a success and the present affair more the fault of the girl than of the husband.

Case 3. The 45-year-old wife of a Captain with 17 years' service was admitted to the psychiatric section after an apparent suicide attempt with a sedative. Her husband had found her unconscious on the steps of their home on the evening of admission. According to her husband, her behavior that day had not been unusual. She had served his dinner in the usual manner and then said that she was going for a walk with the dog. Just before leaving she took eight Seconal (brand of secobarbital sodium) capsules, which she previously had been given at another medical installation because of insomnia.

Interview with the husband revealed that during their 13 years of marriage there was little real affection between them, and that he had never considered the marriage a great success. He had, however, con-

tinued to live with his wife since there were no actual quarrels or disagreements. Recently he had met a girl with whom he believed he was in love. Several weeks prior to his wife's suicide attempt he had openly stated that he no longer loved her and wanted her to return to the United States. She refused to do so, and he had continued to go out with the girl. During this time his wife suffered from insomnia and irritability. He realized that this was a rather unusual situation but felt that it was more convenient to live with his wife than move into the bachelor officer's quarters. One of his chief complaints about his wife was that she seldom gave him encouragement or support.

The patient's past history was characterized by chronic depression and several previous suicide attempts which had resulted in hospitalization. Her life had been rather colorless and she had few outside interests. There were no children, and neither she nor her husband particularly desired any. She felt, however, that hers had always been an "ideal marriage" and did not understand her husband's present attitude. She blamed the girl friend for her difficulties and expressed no overt hostility toward her husband. Although she was a licensed laboratory technician and had held a good position prior to joining her husband overseas, she was fearful about being without her husband's financial support. She had made no effort to seek legal advice regarding support in the event that she was divorced.

On entry to the hospital she was comatose, but completely recovered from the effects of the sedative after 24 hours. She was discharged after six days and followed as an outpatient. She was finally able to think about her future and past life more realistically and sought legal advice for her marital problem.

Comment. This patient's life had been characterized by denial of difficulties and repression of hostility. The marriage might have continued in much the same pattern if the husband had not gone overseas and found a woman who seemed to meet his needs.

DISCUSSION

Most of the cases presented a similar picture: a passive woman married to a relatively narcissistic man. The wife was unable to meet the neurotic needs of her husband. This did not lead to significant marital difficulties until the husband arrived overseas and met a woman who bolstered his self-esteem and at the same time satisfied his dependency needs. When this happened and the husband requested a divorce, the wife was totally unprepared to meet the situation in a realistic manner. In many instances the husband candidly admitted having a girl friend but continued to live under the same roof with his wife. This unrealistic and stressful situation was largely the result of the unique housing situation for dependents overseas. In all cases attempts were made to understand the personality characteristics and needs of both husband and wife, and to apply this knowledge toward improving their interpersonal relationships.

The large number of cases observed emphasized the extent of emotional disturbances in the dependent wives of servicemen and officers in an overseas theater. No attempt was made to include cases in which the marital problem was a minor one. In all these cases there was a serious marital problem, apparently directly related to the unique stresses of an overseas theater. All of the cases seen were of neurotic women whose marriages were only superficially stable or meaningful before their husbands went overseas. In those instances in which the husband deserted his wife for another woman primarily because of his own neurotic needs, he appeared to be more neurotic than the wife. It is believed that many of these marriages would have remained superficially stable had both partners remained in the United States. In some cases prompt legal separation or divorce probably would have decreased the emotional disturbance in the wife. A wife living in the same house as her husband and aware of her husband's interest in another woman is caught in an impossible situation.

The actual extent of marital problems is even more serious and widespread than would be suspected from the number of cases mentioned here. Many persons with marital problems resulting from the stresses of being overseas do not come to the attention of the psychiatrist but seek medical advice for various symptoms of anxiety. Some marital problems are never brought to the physician because of fear that the husband would be disciplined and the whole family suffer financial and other consequences.

CONCLUSIONS

The importance of recognizing and dealing with the emotionally disturbed patient in terms of his interpersonal relationships is often neglected. This is clearly illustrated by the number of patients with severe marital problems that go unrecognized because of failure to take the patient's total life situation into consideration. Such severe marital conflicts are more likely to occur in an overseas theater and are probably aggravated by some administrative policies. There are certain unique circumstances encountered by military personnel and their families overseas which adversely affect harmonious family life in general and marital adjustment in particular. It is suggested that efforts should be made to reduce some of the unique stresses in an overseas theater. The early recognition of such cases by medical officers might also help prevent the more serious types of emotional disturbance encountered.

SUMMARY

In one year, 173 dependent wives of servicemen were seen for psychiatric evaluation at an overseas Army hospital. Thirty-one of these patients had emotional disturbances resulting from serious marital problems.

During overseas service, unique disruptive factors increase family problems and marital difficulties in general. The medical officer must recognize the effect of these disruptive influences when evaluating emotional disturbances in military personnel overseas.

STRESS AND THE MILITARY

"Men with strong passive dependency drives who have functioned efficiently in combat and were promoted rapidly find it stressful, while separated from their families, to adapt to a peace-time Army routine involving assumption of full responsibility of grade in new units.

"Peace-time assignment of career soldiers to the locale in which they first were in combat can serve as a stressful element in persons who are not emotionally mature and who hold strong negative nationalistic prejudices."

Lethal Midline Granuloma and Periarteritis Nodosa

BYRON G. McKIBBEN, *Colonel, MC, USA*

MILWARD W. DAYLISS, *Colonel, MC, USA*

CASES of *granulomatous ulceration*, having their primary site in the midline tissues of the face, usually running an indolent course, even appearing to heal at times, but eventually ending fatally, occasionally have been reported in medical literature.¹ Similar cases of granuloma of unknown cause were reported as far back as 1906.²

Weinberg³ presented two cases of granuloma of unknown cause associated with *periarteritis nodosa*, in which he concluded that the vascular lesions were recent because there was no evidence of healing. He further stated that in all the cases of granuloma of obscure cause that were thoroughly studied and fully reported, *periarteritis nodosa* was a terminal development. In contrast to this, two of the cases adequately studied by Williams¹ failed to show the lesions of *periarteritis nodosa*.

Wegener⁴ described *periarteritis nodosa* as a common finding in patients with lethal granuloma. He believed that the condition causing the granuloma might also be the one causing the *periarteritis nodosa*. Gerlach⁵ described necrosis of arterioles at the site of the Arthus phenomenon. Williams stated that this observation had been confirmed repeatedly and therefore suggested that the same necrotic vascular reaction causing Arthus phenomenon when it involves capillaries is also responsible for *periarteritis nodosa* when it involves somewhat larger vessels.

Williams further concluded that one of the fundamental resistance mechanisms of the animal is a typical cellular immune response, primarily vascular, resulting in the Arthus phenomenon when capillaries are involved, producing a granuloma in deeper tissues or a *granulomatous ulceration* if skin and subcutaneous tissues are involved; that the *granulomatous ulceration* has a tendency to occur in the midline of the face, but is not confined to this location; and that there is a tendency for the involvement of the larger vessels (*periarteritis nodosa*) to occur in the end stages of the disease.

From Letterman Army Hospital, San Francisco, Calif. The authors are now assigned to the Tokyo Army Hospital, APO 500, San Francisco, Calif.

Kahn⁴ suggested that the reacting areas are sites of tissue hyperimmunity where antibodies formed from insoluble globulins are in excess. During later infections these areas of hyperimmunity extract specific or nonspecific antigens circulating in the blood and localize them with the production of the necrotizing and granulomatous vascular phenomena. He further suggested that allergic persons are the ones who develop these areas of hyperimmunity. This explains the development of the Arthus phenomenon when the body is invaded by bacteria which produce little or no toxin, and also explains the occurrence of this phenomenon in the absence of specific infection in a hyperimmune person, by the activation of highly immunized areas of tissue by nonspecific, nontoxic proteins gaining entrance to the blood stream. It has been shown that necrosin, which is either a euglobulin or is associated with this fraction in exudate and is liberated by injured cells, is a toxic substance capable of causing the central necrosis.⁵

The experimental work of Selye⁶ suggested a relative adrenal cortical dysfunction with excess production of the "salt-active" and relative suppression of the "sugar-active" corticoids. He found that excess sodium ion and an increased pH favor the development of periarteritis nodosa under experimental conditions, whereas elimination of sodium ion together with the giving of acidifying drugs tends to prevent its development. In 1949 Williams commented that the availability of hormones of the adrenal cortex would make possible new approaches to the study of granulomas.

Reports of cases of periarteritis nodosa responding favorably to cortisone or corticotropin began to appear in the medical literature;^{7,8} and some related disorders, such as lupus erythematosus disseminata,¹⁰ asthma, and vasomotor rhinitis,¹² were showing improvement on such treatment.

With evidence pointing toward a relationship between idiopathic granuloma and periarteritis nodosa, Williams and Hochfilzer¹¹ tried the effect of injections of cortisone on a patient in whom the diagnosis was idiopathic granuloma of the midline tissues of the face. While the course of the disease appeared to be altered somewhat favorably, they were of the opinion that cortisone would not prove to be a useful drug in the management of this condition, because of the slowness of healing and the unfavorable side effects, namely, interference with potassium metabolism and production of some general deterioration in the patient's condition.

In 1953 Hagans, Parry, and Markson¹⁴ reported a case of lethal granuloma of the nose and face treated with corticotropin which had remained healed 7 months. Follow-up, 22 February 1956, revealed that the patient had required no further treatment and

had remained entirely well.¹⁵ Full evaluation of this treatment however, awaits its use in more cases.

Early reports on the treatment of disseminated lupus erythematosus and polyarteritis nodosa with cortisone and corticotropin were optimistic, but it became apparent that the treatment was supportive only, and in no sense curative of the disease.¹⁶

Malkinson and Wells¹⁷ reviewed the therapeutic results of adrenal steroids on periarteritis nodosa and in conclusion stated that corticotropin and cortisone were the most effective agents for the treatment of this condition, despite serious disadvantages; that their use must be weighed carefully in each instance, and that one may expect the best results in a relatively young patient in whom treatment is started prior to the development of extensive visceral lesions and continued with proper dosage long enough for abatement of abnormal signs, symptoms, and laboratory findings.

The treatment of lethal midline granuloma remains obscure, and because of the rarity of this condition, it is not believed that a clear-cut regimen can be outlined in the near future. Until this condition is better understood, and in view of its apparent close causative relationship to periarteritis nodosa, it is suggested that measures which are found to be of value in the latter condition also be tried on lethal granuloma, and that when cortisone or corticotropin are prescribed, they be given in accordance with the principles suggested by Malkinson and Wells.

CASE REPORT

A 33-year-old white housewife was first seen in the ear, nose, and throat clinic of a U. S. Army hospital in Germany, 6 November 1952, with a complaint of difficulty in breathing through the left nostril. She stated that she had felt well until early October 1952, when she became aware of a slight nasal obstruction and pinkish color on her handkerchief after blowing her nose. She thought she had a cold and paid little attention to her symptoms.

Approximately five weeks before the onset of the nasal symptoms, she had noticed a small, tender nodule in each buttock, and one in the medial aspect of the left thigh. She had a cholecystectomy scar which was intermittently tender, and it was during a hospitalization for surgical revision of this scar and excision of the nodule in the thigh that she was seen by the otolaryngologist.

Past history and family history revealed that she had had one tubal pregnancy treated surgically. Two other pregnancies terminated in the birth of normal children. In 1946, she had a chronic cough for three months, followed by bronchial pneumonia. She was treated with sulfadiazine and was confined to her bed for 12 days. During the convalescent period she was troubled with pain in the right side of the chest posteriorly. Recovery was complete.

CASE REPORT

A 33-year-old white housewife was first seen in the ear, nose, and throat clinic of a U. S. Army hospital in Germany, 6 November 1952, with a complaint of difficulty in breathing through the left nostril. She stated that she had felt well until early October 1952, when she became aware of a slight nasal obstruction and pinkish color on her handkerchief after blowing her nose. She thought she had a cold and paid little attention to her symptoms.

Approximately five weeks before the onset of the nasal symptoms, she had noticed a small, tender nodule in each buttock, and one in the medial aspect of the left thigh. She had a cholecystectomy scar which was intermittently tender, and it was during a hospitalization for surgical revision of this scar and excision of the nodule in the thigh that she was seen by the otolaryngologist.

Past history and family history revealed that she had had one tubal pregnancy treated surgically. Two other pregnancies terminated in the birth of normal children. In 1946, she had a chronic cough for three months, followed by bronchial pneumonia. She was treated with sulfadiazine and was confined to her bed for 12 days. During the convalescent period she was troubled with pain in the right side of the chest posteriorly. Recovery was complete.

Examination of the nose on 6 November 1952 revealed an area of ulceration on the left side of the nasal septum and another on the medial surface of the anterior portion of the left inferior turbinate. The cardiolipin test for syphilis was negative. Complete blood cell count and urinalysis were normal.

On 7 November a tender nodule in the cholecystectomy scar and one in the left thigh were excised. Histologic examination showed large central areas of scarring granulation tissue with scattered microabscess-like features. Eosinophils were prominent and there were a few macrophages laden with brown and granular pigment. The diagnosis was granulomatous panniculitis (fig. 1).

Figure 1. Photomicrograph of section of the nodule from the buttock showing granulomatous panniculitis with infiltrate composed of lymphocytes, plasma cells, neutrophils, and eosinophils. The wall of the small arteriole in the center has a smudgy appearance due to fibrinoid degeneration. (Hematoxylin and eosin stain, $\times 100$)

On 14 November biopsy specimens were removed from the nasal lesions, which by that time had extended to the right nasal fossa. The tissue was soft, friable, and bled easily, and the nose was very tender and painful. Histologic examination showed acute and chronic inflammation (fig. 2). Cultures from this material showed a moderate growth of hemolytic *Micrococcus pyogenes* var. *aureus* (*Staphylococcus aureus*), *Micrococcus pyogenes* var. *albus* (*Staphylococcus albus*), and *Corynebacterium xerose*.

The patient had been noticing an increasing deafness and pain in the right ear. On 25 November, the right tympanic membrane perforated spontaneously, releasing sanguinopurulent material. The patient was admitted to the hospital the following day. Culture from the aural dis-

charge and from the right nostril showed a heavy growth of hemolytic *M. pyogenes* var. *aureus*, moderately sensitive to streptomycin sulfate and chlortetracycline hydrochloride (aureomycin). Cultures for yeast and fungi were negative. One gram of streptomycin sulfate was given daily from 28 November to 11 December, when, because the patient's condition had not improved, the dose was doubled. Both nasal cavities were almost completely closed and the ulcerated areas were surrounded with friable-appearing mucosa which bled easily. The pain in her ear became almost unbearable, and she was depressed and cried at times.

Figure 2. Nasal biopsy. Section showing acute and chronic inflammation with a dense infiltrate of neutrophils, eosinophils, lymphocytes, and plasma cells. (Hematoxylin and eosin stain, $\times 200$)

By 19 December she was showing a little improvement, the pain was less severe and she was allowed to return to her home for the holiday season. Streptomycin sulfate was discontinued and 500 mg of chlortetracycline hydrochloride, four times daily, was prescribed.

The patient's condition continued to improve until 19 January 1953, when her hearing again became poor and there was recurrence of pain in her ears and nose. Shortly after this, an area of swelling associated with severe pain developed below the left eye, and she was again admitted to the hospital.

At that time it was noted that she was having a great deal of difficulty in hearing, the masses in the buttocks had increased in size, the nasal lesions were more extensive, acute dacryocystitis had

developed on the left side, and she had lost 23 pounds since the onset of her illness. The swelling under the left eye became fluctuant and on 2 February it was incised and allowed to drain.

The patient was transferred to an Army general hospital, and on 10 February two large masses were removed from the right buttock and one from the left buttock. Histologic examination showed acute and chronic inflammatory infiltrate, including neutrophilic and eosinophilic polymorphonucleocytes, lymphocytes, plasma cells, monocytes, foam cells, and multinucleated foreign-body type giant cells. There were areas of necrotic foci, some of which were seen grossly as soft central areas. The fibrous stroma varied from a very cellular to hyaline structure. There was no evidence of epithelioid tubercle formation. During this hospitalization the white blood cell count had dropped to 6,200 per μ l on one occasion and to 4,300 on another, with a normal differential count. Hemoglobin was 9.8 g per 100 ml. Repeated cultures of secretions showed hemolytic *M. pyogenes* var. *aureus* sensitive to penicillin and chlortetracycline hydrochloride. The urine remained normal. Her record did not show treatment for anemia or leukopenia, and she was discharged from the hospital on 21 February 1953.

She was readmitted to the hospital on 4 March, complaining of pain in both ears and nose. Examination showed the right tympanic membrane to be perforated and there was bloody discharge. The left tympanic membrane was bulging. There was a small healing lesion in the left lower eyelid. The incision over the lacrimal sac was healed. There was a large perforation through the cartilaginous portion of the nasal septum. Tuning-fork tests indicated a marked conduction deafness. White blood cell count was again normal, red blood cell count was 4,840,000 per μ l, and the hemoglobin was 12.7 g per 100 ml. Tuberculosis of the nose was suspected, and the patient was transferred to an Army general hospital where the diagnosis was thought to be eosinophilic granuloma of the nose, paranasal sinuses, left nasolacrimal duct, ears and temporal bones, and subcutaneous tissues of the buttocks and thighs. She was evacuated to the United States, arriving at this hospital 14 April 1953, where she was admitted on the otolaryngology service.

Examination revealed a thin, chronically ill woman, moderately depressed and in obvious discomfort. The patient's entire room was filled with a putrid odor. Her blood pressure was 118/70 mm Hg. Her temperature was normal. She spoke with difficulty because of numerous small tender lesions in the mouth. A deep ulcer, with raised erythematous edges, was noted just below, and medial to, the left eye, which was held closed most of the time (fig. 3). The right tympanic membrane was lusterless. The left tympanic membrane was retracted and there was a foul discharge although a perforation was not seen. Hearing was greatly diminished and tuning-fork tests indicated bilateral conduction deafness. Both nasal passages were greatly diminished in size because of granulomatous, ulcerating masses on all surfaces.

The septal perforation, previously mentioned, was noted. The lesions on the buttocks were still draining, and small tender subcutaneous masses were noted on both shoulders and on the anterior aspect of the right thigh. The liver was palpated three fingersbreadth below the costal margin and was tender. The spleen was palpated two fingersbreadth below the costal margin and was not tender.

Figure 3. Granulomatous ulceration of the face, apparently originating in the nasolacrimal tract. Autopsy demonstrated a sinus tract leading to an ethmoid cell.

A tentative diagnosis of lethal midline granuloma was made. This was concurred in by the otorhinolaryngology consultant who advised that the secondary infection be brought under control with adequate antibiotic therapy and that the patient be given a course of cortisone. The medical consultant, while agreeing that the condition could be one of the collagen diseases, strongly advised against cortisone because of the danger of causing a widespread dissemination of the infection. The surgical consultant said he had never seen anything quite like it and suggested that an anaerobic infection might be the cause.

Biopsy specimens revealed a granulomatous inflammation of undetermined cause in a nodule on the right thigh, acute and chronic inflammation of the nasal mucosa, and necrotic tissue in a specimen from the tongue.

Roentgenograms of the sinuses showed marked thickening of the mucous membrane of the right maxillary sinus and complete cloudiness of the left maxillary sinus. There was no evidence of pathologic change in the bones of the skull.

Culture from the nasal mucosa grew nonhemolytic *M. pyogenes* var. *aureus* sensitive to chlortetracycline hydrochloride, Terramycin (brand

of oxytetracycline), Chloromycetin (brand of chloramphenicol), and erythromycin. Smears and cultures for acid-fast bacilli were negative. Guinea pigs inoculated with material aspirated from the left maxillary sinus and obtained by biopsies of the nasal mucosa and a subcutaneous nodule died prematurely of causes other than tuberculosis.

Between 17 and 23 April the patient was given x-ray therapy: 450 r (in air) to an 8- by 11-cm frontal portal and an equal dose to a 10- by 10-cm left lateral portal, with no significant improvement.

Because of the widespread involvement, the patient was transferred to the medical service on 25 April for general care. She continued to be seen daily by a member of the otolaryngology service.

Five hundred milligrams of chloromycetin, four times daily, was prescribed, pending the result of sensitivity studies being made in Dr. Brainard's laboratory at the University of California.

On 29 April it was the consensus at a medical conference that there was some unknown abnormality in the patient's body defense mechanism that could possibly be a lethal midline granuloma, but that the most obvious treatable disease was the widespread micrococcus infection, which was thought to be secondary. Sensitivity tests, run at the University of California, revealed that the organism was highly sensitive to chlortetracycline hydrochloride and relatively insensitive to all other antibiotics tested. Treatment was therefore changed from Chloromycetin to chlortetracycline hydrochloride in the same dosage. A Levine tube was passed into the stomach for the administration of medications and feeding formula.

Repeated blood cultures showed no growth. By 3 May the patient was beginning to show slight improvement; the nodules on the and thighs appeared reduced slightly in size but the about the nose and upper lip had extended somewhat. The next number of deep red purpura-like spots were noted on the aspect of both legs. The subcutaneous lesions, however, to improve. By 18 May, the purpuric lesions had begun to fade, liver and spleen were no longer palpable, her mouth and she was able to sit in a chair for short periods. By 30 could breathe some through her nose, and the wounds on appeared to be improved. On 11 June, it was noted that had dropped to 7.8 g per 100 ml. She was, therefore, fusions of whole blood (500 ml each). She was still chlortetracycline hydrochloride four times daily.

On 17 June examination revealed three areas of perineum. One of these areas was excised and h showed nonspecific granulomatous inflammation.

By 22 June improvement had come to a stand was beginning to show some signs of going down by increasing anorexia, mild mental

elevations, and a mild drop in blood pressure (90 to 100 mm Hg systolic and 64 to 72 diastolic).

On 25 June culture from a buttock wound was reported as showing *M. pyogenes* var. *aureus*, sensitive only to Chloromycetin and bacitracin, and pseudomonas resistant to all antibiotics tested. Hemorrhagic lesions developed on the back of the patient's left hand, and small vesicles were noted over the left forearm and anterior chest. The liver and spleen were again palpable. The patient was unable to tolerate Chloromycetin, and was started on 25 mg of cortisone every six hours and 1 gram of potassium chloride three times daily. Her course was rapidly downhill, with increasing hemorrhagic skin lesions, marked perspiration, temperature of 102°F, and generalized nervous twitchings, and she died 30 June.

Autopsy. Autopsy performed 10 hours after the patient's death revealed the following pathologic processes which had not been observed previously.*

1. Necrotizing panarteritis (periarteritis nodosa) involving vessels of the stomach, intestines, liver, kidneys, and bladder. There were a few arteries in the kidneys and one in the liver in which fibrosis suggested healed panarteritis (fig. 4).

Figure 4. Connective tissue of the liver containing partially healed lesion of periarteritis nodosa in a small artery. This artery is practically obliterated by scar tissue while only a few inflammatory cells and a slight amount of fibrinoid material remain. (Hematoxylin and eosin stain, $\times 100$)

*Gross and microscopic examination was performed by Captain Joseph H. Masters, and the slides were reviewed by Dr. Alvin J. Cox, Major T. R. Anderson, and one of us (M. W. B.).

2. Inflammatory angitis of the lungs, kidneys, adrenals, and skin.
3. Mucosal ulceration of the stomach and intestines.
4. Necrotizing granulomatosis of the lungs and kidneys.
5. Necrotizing bronchitis.
6. A sinus tract leading from the infraorbital ulceration to an ethmoid cell.
7. Blood culture (heart) revealed hemolytic *M. pyogenes* var. *aureus*, coagulase-positive.

COMMENT

It is interesting to note that there was some evidence of healed panarteritis in the kidneys and liver. Although the main picture was one of extensive inflammation and necrosis, there were a few fibrosed arteries, lacking in inflammatory cells, suggesting focal areas of healing or healed panarteritis. While periarteritis nodosa has been considered to be a terminal development in cases of idiopathic granuloma,^{1,2} this observation indicates that some of the vascular lesions had developed in an earlier stage of the disease.

SUMMARY

A case of lethal midline granuloma associated with periarteritis nodosa is presented. While periarteritis nodosa tends to be a terminal development in cases of idiopathic granuloma, the finding of a few focal areas of healed panarteritis in this case is evidence that these healed lesions, at least, developed during an earlier stage of the disease.

The two conditions (lethal midline granuloma and periarteritis nodosa) appear to be the result of hyperimmunity, causing the granulomatous lesions when capillaries are involved and periarteritis nodosa when somewhat larger vessels are involved.

Cortisone or corticotropin, in order to be of any benefit in the treatment of lethal granuloma or periarteritis nodosa, should be given early in the course of the disease, in adequate dosage and with careful supervision.

EVALUATION OF DISCOID LUPUS

"The classification of lupus erythematosus is an arbitrary one. There are many transitions between the types. Discoid lupus, from its inception, is a systemic disorder which is a variant of the more malignant acute disseminated form. The "benign"-appearing cutaneous lesion may be a herald of advanced systemic manifestations which may be present at the same time or at a later date, when the skin changes have healed. Therefore, all these patients should have a thorough general medical survey. The form of therapy instituted depends entirely upon the extent of the disease."

Placenta Accreta

JOHN R. O'BRIEN, M. D.

CHARLES C. SORENSON, Major, USAF (MC)

GORDON W. SCOTT, Captain, USAF (MC)

FREDERICK SILVERMAN, Captain, USAF (MC)

PLAGENTA ACCRETA is "an abnormal adherence of part of the placenta or all of it to the uterine wall with partial or complete absence of the decidua basalis, especially the spongiosum layer."¹ Based on the depth of invasion of trophoblastic elements, Kallreider² classified the condition as: (1) placenta accreta (pathologic adherence only), (2) placenta increta (penetration of uterine wall), and (3) placenta percreta (uterine wall penetrated to or through serosal layer, and in some cases ruptured). A second classification describes the surface extent of the abnormal placental attachment: focal, partial, or complete.³

The main causal factor appears to be injury to the endometrium by trauma, infection, an associated obstetric or gynecologic disorder, or an endocrine imbalance. Traumatic causes include previous manual removal of an adherent placenta leaving scars, dilatation and curettage, therapeutic abortion, radium therapy, and cesarean section. Infections include tuberculous peritonitis and endometritis. Fibroids, diverticula, placenta praevia, cornual implantation, placenta membranacea, and adenomyosis have been listed as associated obstetric or gynecologic disorders. A defective corpus luteum might contribute to an endocrine imbalance leading to placenta accreta.^{1,4-6}

Various estimates as to incidence range from 1:1956 (Irving and Hertig⁷) to 1:25,000 (Chern and Rosenberg⁸). Greenhill¹ believed it to be 1:2,000; Chisholm,⁴ from 1:200 to 1:20,000; and Phanouf⁹ found an occurrence of 1:14,622 in his survey. Eastman¹ did not observe a single case of complete accreta in over 70,000 deliveries. Only a few more than 200 cases were recorded up to 1953.¹ Israel, Siegel, and Rubenstein¹⁰ stated that a total of 31 cases of simultaneous placenta praevia and accreta had been recorded in the literature up to 1955.

Clinically, there is only a failure to expel the placenta normally. Normal separation from areas totally lacking in decidua is impossible. With complete accreta no bleeding is present because all of the placenta is adherent. Some retained placentae

may be focal placenta accretae, with multiple fibrous attachments to the uterus. Partial accreta is often accompanied by the severe bleeding associated with partial separation. In rare instances, hemorrhagic shock may be associated with spontaneous rupture of the uterus and/or trophoblastic erosion of large uterine artery branches, leading to massive intra-abdominal hemorrhage. Other factors which may cause hemorrhage are placenta praevia, traumatic attempts at manual removal leading to rupture of the uterus, rupture by a curet, or inversion of the uterus.^{1,9,11} Diagnosis is made by failure to find a cleavage line in attempting atraumatic manual removal of the placenta.

The treatment of choice for almost all patients is listed in standard texts as immediate abdominal hysterectomy once the diagnosis is made.^{1,9,12} Muir¹¹ reported a case in which the placenta of a four and one-half month abortus could not be removed manually. There being virtually no bleeding, the patient was put to bed and given antibiotics. By eight weeks, uterine drainage had ceased. Two months later the patient became pregnant, going on to a normal delivery and third stage. Greenhill¹ cited 14 cases in which the placenta was allowed to remain intact without an attempt at removal. All 14 women survived. Others⁴⁻⁶ urge conservative treatment when possible. It is recommended that the therapy chosen should depend on the amount of bleeding and the uterine response to complete or partial removal of the placenta. In complete accreta with little bleeding, the placenta should be drained of fetal blood and allowed to become organized and absorbed. With partial accreta too densely adherent to be removed, the uterus should be packed and treated expectantly. Unfortunately, even with adequate blood replacement this rarely suffices, and hysterectomy becomes the treatment of necessity. Israel, Siegel, and Rubenstone recommended that with combined placenta praevia-placenta accreta discovered at cesarean section, hysterectomy be done. The following case report describes an attempt at conservative therapy for partial accreta which failed, and for which hysterectomy was necessary.

CASE REPORT

A 26-year-old woman, gravida 2, para 1, whose estimated date of confinement was 30 June 1955, was admitted to the maternity ward of this hospital at 2100 on 10 July with a history of cramping pain in the lower abdomen of several hours' duration. The pain ceased soon after admission. The patient was discharged the following morning, to be seen shortly in the prenatal clinic. She was readmitted on 14 July at 2300, with the bag of waters having ruptured earlier at home.

The prenatal course was marked by a moderate degree of polyhydramnios and a marked diastasis recti abdominis. Blood pressure determinations and repeated urinalyses were always within normal limits.

Hematocrit on 7 July (one week prior to delivery) was 38 ml per 100 ml, with a hemoglobin of 12 g per 100 ml. A roentgenogram of the abdomen taken on 7 July revealed a single fetus, near term, in cephalic presentation, with an unusually large amount of fluid present.

The previous obstetric history was that of one previous pregnancy in 1954, highlighted by mild post-partum atony of the uterus, and death of the 7 lb 7½ oz newborn infant 32 hours after birth due to massive intracranial hemorrhage, secondary to a right tentorial laceration.

Uterine contractions began at 0200 on 15 July. The first stage of labor ended at 0600. A saddle block anesthesia, using 3 mg of Pontocaine (brand of tetracaine hydrochloride) was performed at 0610. However, it was concluded shortly thereafter that the patient was not ready for delivery. She was returned to the first-stage room to be kept under close observation. Fetal heart tones remained good, as did maternal pulse and blood pressure.

At about 0945, a posteroanterior and left lateral roentgenogram of the abdomen and pelvis were taken showing the fetus in right occiput transverse position at +2 station.

At 1015, 4 hours and 15 minutes of the second stage having elapsed since the saddle block anesthesia, the patient was returned to the delivery room. Blood was drawn for typing and cross-matching. An infusion of 5 per cent dextrose in water was started. Penicillin and streptomycin sulfate were administered intramuscularly. The blood pressure at 1015 was 94/50 mm Hg. The patient was prepared, draped, and catheterized, and anesthetized with a pudendal block using 1 per cent Xylocaine (brand of lidocaine hydrochloride). At 1035, 75 mg of Demerol (brand of meperidine hydrochloride) were given intramuscularly, putting the patient to sleep.

Manual rotation of the head was unsuccessful, as was the use of Simpson's forceps via the wandering technic. The patient was delivered with Kielland's forceps, using the inversion method of application, of an 8 lb 10 oz male infant. The baby was in fair condition. Normal respiration was established in approximately 40 seconds.

The mother was given a 1 ml-ampule of Pitocin (brand of oxytocin) intramuscularly after delivery, at 1127. A transfusion of blood (500 ml) was started at 1134. Blood pressure at this time was 108/70 mm Hg and the pulse 84. One hour of the third stage elapsed without spontaneous delivery of the placenta, prior to an attempt at manual removal. A portion of the placenta was removed piecemeal. It was impossible to find a line of cleavage for all of the placenta. One milliliter of Ergotrate (brand of ergonovine maleate) was given intravenously. A 6-cm cervical laceration of the anterior lip was repaired. At 1245 blood pressure was 90/60 mm Hg and the pulse 92. By 1410, 1,000 ml of whole blood and 500 ml of dextran had been administered. Excessive bleeding, after repair of the cervical laceration, was encountered and

felt to be due in large measure to uterine atony. The uterus was thoroughly packed in what proved to be an unsuccessful effort to treat the atony.

At 1500, the patient was taken to the operating room. The packing was removed, the uterus re-explored, and the diagnosis of placenta accreta was confirmed. In view of the marked uterine atony, with consequent extensive bleeding, a rapid total hysterectomy was performed under general anesthesia. Blood was replaced in adequate quantities. The patient left the operating room with a pulse of 84, and a blood pressure of 110/84 mm Hg.

On opening the specimen, an 8- by 8-cm portion of placenta was noted to be tightly adherent to the anterior wall of the uterus. A 2-cm laceration was present at the left lateral aspect of the lower uterine segment. The cervical laceration had been entirely repaired.

Postoperatively, the blood pressure and pulse were maintained within normal limits. Therapy included adequate fluid and electrolyte replacement, massive doses of antibiotics, and multiple blood transfusions. The patient received a total of 3,500 ml of whole blood during her hospital stay. Spiking temperatures were present until the fifth postoperative day. The patient was discharged on the tenth postoperative day in good condition.

The pathology report by William A. Meriwether, Captain, MC, USA (6th Army Area Medical Laboratory, Fort Baker, Calif.) and confirmed by the Armed Forces Institute of Pathology noted grossly an area of undetachable placenta adherent to the uterine wall. Microscopically, "cotyledons were lying adjacent to the uterine musculature, separated only by an occasional decidual cell" (figs. 1-3).

Final diagnosis: Placenta accreta, partial.

COMMENTS

As previously noted, conservative therapy for partial placenta accreta is rarely successful. The occasional success, however, warrants a trial in young women of low parity, provided the patient is closely observed and adequate blood replacement is at hand.

In the case reported, the uterine atony encountered was apparently due to a combination of factors, namely, overdistention of the uterus, a greatly prolonged second stage, too vigorous attempts at manual removal of the placenta, and possibly, the rent in the lower uterine segment. A previous obstetric history of traumatic delivery and post-partum atony indicated the need for cautious management of the second and third stages of labor.

Figure 1. Low power view of cotyledons lying adjacent to uterine musculature. ($\times 100$)

Figure 2. Medium power view of villi adjacent to uterine musculature. ($\times 430$)

Figure 3. High power view of villi adjacent to uterine musculature separated only by an occasional decidua cell.

SUMMARY

A reported case of partial placenta accreta illustrates the fact that this condition usually warrants hysterectomy, total hysterectomy being the treatment of choice.

THE CASE FOR HYSTERECTOMY

When the health of a woman, physically and emotionally, is compromised by an abnormal uterus to a serious degree (and the judgment of this degree of disability is squarely on the shoulders of the conscientious surgeon performing hysterectomy), excision has proved one of the most satisfactory procedures in all surgery. The emotional confusion in consideration of the sexual organs, femininity, and procreation has prevented some from seeing or realizing the great importance of extending hysterectomy to those in dire need of it. Hysterectomy should never be performed for minor complaints and minor findings, but only when there are major diseases or when those complaints and findings add up to a major disability.

p. 500, Oct. 1954

Spinal Cord Pseudotumor

A Complication of Pantopaque Myelography

SARKIS S. SARKISIAN, *Commander, MC, USN*

WHEN radiopaque substances are injected into the spinal canal in myelography, an occasional local tissue reaction should be expected. Such a reaction was seen in a patient who had been evaluated for spinal cord tumor.

CASE REPORT

A 39-year-old woman had first noted urinary stress incontinence following an episode of viral pneumonia. This symptom gradually became worse, and on 4 January 1956 a myelogram was done, using Pantopaque (brand of iophendylate). This was repeated on 2 February. No tumor was revealed by either of these examinations.

On 29 February the patient noted the onset of numbness over the sole of the left foot, in the perineum, and along the back of the left leg. The physical examination and past history supplied no other pertinent information. The neurologic examination showed slight hypalgesia of S3, S4, and S5 segments. The impression was: cauda equina lesion with cord compression. A third myelogram on 15 March was interpreted as showing a tumor at the L5-S1 level. The filling defect measured 1 by 3/4 cm and was constant, suggesting a spinal cord tumor in this area (fig. 1).

On 21 March a laminectomy of L5, S1, and S2 was performed. This revealed an inflammatory subdural tumor mass, as much as possible of which was removed. There was an uneventful recovery, and one month postoperatively the patient was much improved. The tumor (fig. 2) was a lipoid granuloma composed of fibroblastic cell proliferation, foreign-body-type giant cells, and "punched-out" areas representing lipoid material.

DISCUSSION

Before Pantopaque was first used in clinical trials, Steinhausen and associates¹ studied its effects on dogs. They reported foreign body response when the oil was injected intrathecally, with encystment within about six weeks. When used in humans, Pantopaque has given excellent results generally. Marcovich, Walker, and Jessico² reviewed 150 cases in which iodized oil had been

used to examine the spinal cord and found no deaths referable to the injection. Bering¹ reported on a series of 106 cases in which he used Pantopaque with no untoward results, except for a single case where the Pantopaque became fixed in one mass. Arbuckle, Sheldon, and Pudenz² and Peacher and Robertson³ reported over 400 additional cases with no unusual findings.

Figure 1. Roentgenograms revealing constant filling defect at L5 and S1 level.

On the other hand, Camp⁴ reported encystment of Pantopaque subsequent to myelography. Luce, Leith, and Burrage⁵ described two cases of delayed noninfectious meningitis with spinal fluid findings of increased protein and inflammatory cells. Erickson and van Baaron⁶ reported a case presenting manifestations of late meningeal reaction with fatal termination, in which autopsy revealed a fibrinous exudate over the base of the brain and thoracic spinal cord, with microscopic evidence of widespread dispersion of oil.

Fine emulsification of the oil may introduce an additional hazard that must be considered during myelography. In fact, Jaeger⁷ showed that in dogs intrathecal injection of emulsified Pantopaque caused death in 10 minutes. It would seem that a bloody tap should be considered a contraindication for the injection of oil intrathecally, for blood can cause emulsification of the oil.

Figure 2. Photomicrograph of section of spinal cord lesion revealing typical lipid granuloma. ($\times 200$) (Medical Illustration Section, First Army Area Medical Laboratory)

CONCLUSIONS

It is necessary to take precautions during any myelographic procedure when a foreign material is injected intrathecally. Injection of oil should be postponed in case of a bloody spinal tap. The iodized oil should not be emulsified with spinal fluid or other material. An attempt to remove as much of the iodized material as possible should be accomplished after completion of myelography. It should be remembered that injection of such materials can elicit local tissue proliferation as well as a systemic sensitivity response.

TEACHERS OF MEDICINE

"One of the diseases of our society is this erroneous belief that the brave new world will come to pass by miracles of structural design and intricate organization alone. Plans there must be, but personalities must take precedence of plans. The basic essential is to ensure that medical students, both undergraduates and post-graduates, are associated with (not just taught by) those whose lives and work are examples of excellence in scholarship and professional skill. These teachers must be ever dissatisfied with their efforts, critical of themselves and others, forever scheming and striving to test the truth of what appears to be known, and planning to enlarge knowledge. Among such there is no room for the complacent, the arrogant, the staunch upholder of tradition, and the stout defender of the status quo. The quality of our teachers is all-important and a heavy responsibility rests on those who have to select the academic staffs and consultants responsible for medical education."

—W. MELVILLE ARNOTT, M. D.
in *Lancet*, p. 785, Oct. 15, 1955

A MESSAGE FROM THE A. M. A.

No project initiated by the American Medical Association in the past 10 years has received wider applause and support than its program of assistance to medical schools in financing their operations. The American Medical Education Foundation was established in 1950 to stimulate voluntary contributions from physicians for use in support of the nation's approved medical schools.

Following World War II, the medical schools faced an expanded enrollment and mounting operating costs. Their teaching programs had to keep pace with the rapid advance of medical science and the broadening concept of medicine's role in the community. The traditional sources of income were insufficient to meet the postwar rising costs and at the same time maintain the high standard of medical education in the United States. It was estimated that at least an additional \$10,000,000 each year was necessary to make up the deficits of the medical schools.

To meet this need, the A. M. A. sponsored the American Medical Education Foundation, which was incorporated to receive donations from individual physicians to help defray the costs of our present-day medical education system and to administer the allocation of these funds. The A. M. A. gave \$500,000, the first donation to the Foundation, and agreed to finance the costs of promotion and administration. As a result, the Foundation is one of the few organizations now raising funds in the United States whose *entire income in contributions goes to the cause for which funds are donated.*

During the past six years, the Foundation has received and distributed \$4,684,312 to medical schools. In 1955, more than 25,000 contributors made individual gifts to the Foundation. The A. M. A. has made grants totaling \$1,100,000, which the Foundation has distributed for the private support of medical schools. It has continued to pay all administrative costs, and exerts every effort to encourage and further the program.

Several policies were established by the Foundation with respect to contributions, one of them being a rule that no donations would be restricted as to use in the medical schools. This policy was necessary since many restricted grants made in prior

From the Council on National Defense of the American Medical Association. The views and opinions expressed are not necessarily those of the Department of Defense.
—Editor

years could not properly be integrated into a medical school's program because of the limited administrative and housekeeping facilities of the school. Many deans have expressed their gratitude for this rule that permits freedom of utilization and thereby makes the actual grant worth many times its face value.

Another policy adopted early was the acceptance from physicians of donations specifically earmarked for the school of their choice. This was done so that full expression could be made of the physician's loyalty to his alma mater. The rule also permits the Foundation to co-ordinate its efforts with an active annual alumni giving program. Since 1953 the Foundation has served the medical schools as a clearing house for statistical information in regard to alumni giving. It has reported each year the amount of money given without restrictions directly to each of the medical schools by their alumni.

The success of the American Medical Education Foundation has largely been a result of the work done by physicians in the constituent and component societies of the A. M. A. Across the nation, state associations have appointed chairmen and committees who have made it their job to tell their colleagues about the importance of support for the medical schools. In the American way, each state has adopted a different attack to this problem. A number of state medical societies increased the dues of individual physicians and allocated the increase to the Foundation. Other state societies have a voluntary entry for the Foundation on their dues statement, and many of the societies give large donations from their state treasuries.

These generous contributions from the societies themselves are matched in many states by purely voluntary appeals made in an organized way at the local level. The importance of the program, however, does not reach everyone's ears at once; so it has been a steady effort in education to acquaint every member of the profession with the existence of the Foundation and its purposes. It is expected that within a short time, the \$2,000,000-a-year goal from the physicians of the nation will be reached.

One of the questions constantly asked is how this money is used. Unsought replies to this question pour in from the medical schools. Deans constantly write in gratitude to the Foundation, describing the importance of this source of income. One medical school dean was able to raise the salaries of his instructors enough to show them that the school was appreciative of their services and thus hold his faculty, whereas he had been in danger of losing them because he had no other source of income for these raises. Another dean reported that it would have been impossible for him to increase the seating capacity of several classrooms if it had not been for grants received from this source.

As the costs of everything spiral these days, and a greater teaching burden is placed upon the medical schools by the expansion of medical knowledge, the support of the 82 medical schools of this country as they have always been supported, by the generosity of private philanthropy, must be continued. The nation's physicians must lead the way.

DEATHS

HALE, Legan Owsley, Major, DC, AUS, of Big Clifty, Ky.; stationed at Fort Jackson, S. C.; graduated in 1946 from University of Louisville School of Dentistry, Louisville, Ky.; appointed First Lieutenant 10 May 1949 and called to active duty 25 May 1949; died 29 June 1956, age 37, at U. S. Army Hospital, Fort Jackson, S. C., of bilateral pneumonia with complications.

McCULLEY, Grace Elizabeth, Lieutenant Colonel, ANC, USAR, of Trenton, N. J.; stationed at U. S. Army Hospital, Fort Carson, Colo.; graduated in 1929 from Newark City Hospital School of Nursing, Newark, N. J.; appointed Second Lieutenant, ANC, 8 July 1942; died 2 July 1956, age 50, at U. S. Army Hospital, Fort Huachuca, Ariz., of hypertensive cardiovascular disease.

NEW NAVAL HOSPITAL IN CUBA

The new 100-bed U. S. Naval Hospital at Guantanamo Bay, Cuba, was dedicated on 28 September 1956. The hospital cost \$2,500,000 exclusive of equipment, and is the first naval hospital to be completely air conditioned. It will replace the temporary building used for many years as the base hospital.

Among the distinguished guests present was Dr. F. B. Berry, Assistant Secretary of Defense (Health and Medical). During the ceremony Rear Admiral B. W. Hogan, Surgeon General, U. S. Navy, accepted the new structure with its latest medical facilities and then turned it over to Captain L. A. Newton, MC, USN, Commanding Officer. In dedicating the hospital the Surgeon General paid tribute to the men and women of the Medical Department of the Navy, saying:

"Here, again, we find—and I am most happy to remark on it—that this grand record in hospitalization in Cuba is due very largely to the magnificent examples of those medical men and women of the Navy who have here preceded us—their examples of love for the Navy, of zeal to advance themselves constantly in knowledge and proficiency, and of devotion to their duties—their example, which is possibly the most to their credit, of kindly consideration and encouragement for their patients.

"It is an anatomical fact, that the heart is halfway between the head and the hand. At the bedside of a sick or wounded bluejacket, the brainy mind of the doctor is very important; as, likewise, the deft and sensitive hand that holds the scalpel is a blessing to the patient, of

Dedicatory address is presented by Rear Admiral Bartholomew W. Hogan, MC, USN, Surgeon General, U. S. Navy. Seated, left to right, are Captain Willard C. Calkins, MSC, USN, Director, Medical Service Corps Division, Bureau of Medicine and Surgery, Department of the Navy; Captain Leslie D. Ekvall, MC, USN, District Medical Officer, 10th Naval District; Captain Lyle A. Newton, MC, USN, Commanding Officer, U. S. Naval Hospital, Guantanamo Bay, Cuba; Doctor Frank B. Berry, Assistant Secretary of Defense (Health and Medical); and Rear Admiral William G. Cooper, USN, Commander, U. S. Naval Base, Guantanamo Bay, Cuba.

vital and paramount value. Above these boons, however, is the supreme Godsend of a kindly heart, the balsam of a cordial smile, the reanimating transfusion the physician gives by his sincere and personal interest in his each and every patient. By passing from hand to hand such a torch of medical excellence, even better in the future than in the past, our Naval Medical Department will one day see fully realized, if not all, at least the majority of the zealous and onward aspirations that now signalize it. . . . I hereby dedicate this hospital to the physical, mental, and spiritual welfare of all military personnel and their dependents. It is furthermore dedicated to all mankind in times of possible disaster."

THE NATIONAL LIBRARY OF MEDICINE

The Armed Forces Medical Library was transferred to the Public Health Service of the U. S. Department of Health, Education, and Welfare on 1 October 1957. The National Library of Medicine Act, signed by President Eisenhower on 3 August 1956, established a National Library of Medicine in the Public Health Service "to assist the advancement of medical and related sciences and to aid the dissemination and exchange of scientific and other information important to the progress of medicine and to public health." The Armed Forces Medical Library forms the nucleus of the National Library.

The Armed Forces Medical Library was founded in 1836 as the Library of the Surgeon General's Office, U. S. Army. It was one of the largest and most important medical libraries in the world. It contained almost a million volumes, representing literature on medicine, dentistry, pharmacy, and allied sciences in all languages and of all times. Its books were loaned to other libraries throughout the United States.

In administering the National Library of Medicine, the Surgeon General of the Public Health Service will be assisted by a Board of Regents consisting of 10 persons to be appointed by the President and confirmed by the Senate. Ex officio members of the Board are the Surgeons General of the Public Health Service, the Army, Navy, and Air Force; the Chief Medical Director of the Department of Medicine and Surgery of the Veterans' Administration; the Assistant Director for Biological and Medical Sciences of the National Science Foundation; and the Librarian of Congress. Colonel Frank B. Rogers, who was the Director of the Armed Forces Medical Library, is the Director of the National Library of Medicine.

The National Library of Medicine Act also authorizes the construction of adequate facilities to house the Library on a site to be selected by the Surgeon General of the Public Health Service at the direction of the Board of Regents.

Reviews of Recent Books

UNITED STATES ARMY IN WORLD WAR II. The Technical Services. The Medical Department: Hospitalization and Evacuation, Zone of Interior, by *Clarence McKittrick Smith*. 503 pages; illustrated. Prepared by the Office of the Chief of Military History, Department of the Army, Washington, D. C., 1956. For sale by the Superintendent of Documents, Government Printing Office, Washington, D. C. Price \$4.

This volume contains a detailed and lucid analysis of the complex problems that faced The Surgeon General in his efforts to administer the hospitalization and evacuation system of the Army in the Zone of Interior during World War II. Thus the problems dealt with are those of medical administration and logistics rather than those of clinical care. They were problems partly of his own making, but were in large part an inevitable corollary of those faced by a military organization—catapulted suddenly to 8 million strong—fighting a global war.

The narrative reflects the broad historical pattern of all the elements of the fighting organization in World War II: the initial unpreparedness—the early period of improvisation followed by attempts to clarify and standardize procedures—and the evolution of new policies and procedures to meet the changing requirements of global warfare.

The discussion is directed solely toward plans, policies, and operations at the level of Surgeon General of the Army, and the narrative "written from his vantage point." A delimitation of scope is necessary, but two observations are pertinent. First, this precludes any account of the viewpoint of the patient—1 individual out of a potential 8 million—caught up in the vast and impersonal "system" designed to maintain combat effectiveness. The reader misses the human element. Second, this delimitation has precluded more than an over-simplified statement of facts about situations peripheral to the Surgeon General's Office. For example, the bare statement that the Air Staff "remained nonetheless unconvinced of the wisdom or desirability of pressing for separate air forces hospitals generally" (p. 175), even in context, does not do justice to a complicated subject. The problem of how much to generalize is, of course, a thorny one for any scholar, and probably no two could ever agree on the exact balance to strike.

The organic structure of the volume is sound, and the complex narrative moves along smoothly. There is a great deal of attention given to detail and documentation which should be of value to future planners. The author has avoided the pitfall of partisanship, and in the mellowed perspective of time has treated colorful and controversial figures with impeccable restraint. This volume, along with other military medical volumes of the period, will form a basic reference library for the serious student or planner. —MAE M. LINK, *Pb. D.*

ESSENTIALS OF DERMATOLOGY, by *Norman Tobias*, M. D. 5th edition. 651 pages; 211 figures; 11 subjects in color. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$8.

This textbook for medical students and general practitioners has been widely used since the first edition appeared in 1941. It does not pretend to exhaustively discuss the etiologic, physiologic, pathologic, diagnostic, and therapeutic aspects of diseases of the skin. It is a brief, practical, and useful text for the student and practitioner.

The book is well illustrated with both black and white and colored plates, and the printing is excellent. Organization of the subject matter is practical and useful. Particularly helpful to the nonspecialist is the section included in each chapter on those aspects of nursing that are particularly germane to the diseases considered.

The chapter on general therapeutic suggestions will prove to be a most helpful guide to the beginner.

Dr. Tobias again has succeeded in presenting a wide and difficult subject in a concise and readable form, yet complete enough for everyday use. This book is highly recommended for students of medicine and the nonspecialist — *VICTOR R. HIRSCHMANN, Col., MC, USA*

SYMPOSIUM ON MYASTHENIA GRAVIS. Papers read at the First International Conference on Myasthenia Gravis, at Philadelphia, Pa., on December 8-9, 1954, under auspices of The Myasthenia Gravis Foundation, Inc., New York. *Henry R. Viets*, M. D., and *George D. Gammon*, M. D., Guest Editors. 742 pages; illustrated. Distributed by The Myasthenia Gravis Foundation, Inc., New York, N. Y., 1955.

This symposium includes 18 manuscripts read at the First International Conference on Myasthenia Gravis at Philadelphia, 8-9 December 1954, under the auspices of the Myasthenia Gravis Foundation.

All the papers are rather brief and to the point. There is a statement of the clinical problem, followed by discussions of the pharmacologic aspects of neuromuscular transmission, pathophysiology of the disorder, the relation of the thymus to the disease, drug therapy and special features of management including thymectomy, myasthenic and cholinergic crises, and pregnancy in myasthenia gravis. The quality of this group of papers reminds one of the excellent series published on neuromuscular disorders by this same journal in 1953.

This symposium is recommended and should be useful to physicians who have the responsibility for the management of patients with myasthenia gravis. — *JOHN W. KEMBLE, Col., MC, USA*

SYNOPSIS OF GYNECOLOGY, Based on the Textbook *Diseases of Women*, by *Robert James Crossen*, M. D., F. A. C. S. 4th edition. 255 pages; 132 illustrations, including frontispiece in color. The C. V. Mosby Co., St. Louis, Mo., 1956. Price \$5.25.

The author states in his preface that the synopsis is intended primarily as a less expensive volume for the student who does not wish

to purchase a larger, more detailed, and expensive textbook. It is also his intent to provide the general practitioner with a small and ready reference guide for the recall of basic principles in diagnosis and treatment of gynecologic disorders as encountered in daily practice.

These intentions have been successfully accomplished, and this book aptly fills an additional need which has been encountered by this reviewer; namely, for a very complete and general review of gynecology as would be desired by the general surgeon, particularly in the armed services, who may encounter few gynecologic conditions in his daily work. To the end that it supplies factual and handy statistical data and many excellent outlines and illustrations, it will serve the young teaching associate in gynecology as an excellent, quick pocket reference. The coverage of the field is most thorough while controversial points and full details are left to the larger text.

—JOHN A. PEASE, *Comdr., MC, USN*

BRAIN MECHANISMS AND CONSCIOUSNESS, A Symposium organized by The Council for International Organizations of Medical Sciences. Established under the joint auspices of UNESCO and WHO. Consulting Editors: *Edgar D. Adrian, Frederic Bremer, and Herbert H. Jasper.* Editor for the Council: *J. F. Delafresnaye, C. I. O. M. S., Paris, France.* 556 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1954. Price \$8.50.

This symposium presents the combined efforts of outstanding research workers from the fields of neuroanatomy, neurophysiology, neurosurgery, psychiatry, and psychology to clarify the scientific knowledge surrounding the neurologic basis of conscious mental processes and behavior. The study utilizes a wealth of new data obtained by serious, painstaking research. Recognizing that communications between various scientific disciplines always present difficulties and that the problem of consciousness in its complexity will not at present yield a simple, common-sense analysis, each discussant in this symposium drives incisively to his points of value. All of the work done emphasizes the increasing importance of a complicated, integrating system between the cortex and subcortical formations, generally described as the centrencephalic system and composed of many topographic subcortical nuclei, association tracks, and diffuse arrangements of neurons.

Every physician and every research worker truly interested in the scientific understanding of the motivation of human behavior and the genesis of consciousness can gain greatly from a study of the various presentations. Particularly interesting to psychiatrists and psychologists will be articles on the psychologic, psychiatric, and psychoanalytic aspects of the problem of consciousness by such outstanding research scientists as L. S. Kubie, D. McK. Rioch, H. H. Jasper, A. E. Fessard, K. S. Lashley, and others. Detailed neuroanatomic, neurophysiologic, and neuropathologic presentations by H. W. Magoun, G. Moruzzi, E. D. Adrian, W. Penfield, W. Grey Walter, and others will

greatly interest research workers concerned with resolving the location of consciousness.

Since "consciousness is a primary fact of existence" (D. O. Hebb) and one can only know "the inner world of consciousness directly, the outer world only by inference from the inner data" (J. C. Eccles), it must be recognized that an understanding of consciousness requires both the observer and the observed. This symposium provides a ring-side seat from which either the observed or the observer can truly delve into the mystery of consciousness. This publication should be readily available as a reference book wherever serious study of brain mechanisms and consciousness is carried on.

—LUCIO E. GATTO, Col., USAF (MC)

ARTHIROPLASTY, by St. J. D. Buxton, M. B., B. S. 126 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1955. Price \$6.

This monograph is an attempt to cover the subject of arthroplasty of the various joints, including significant historical data and a review of recent contributions by other surgeons, and concluding with a cautious chapter of predictions on what the future holds. The bibliography is complete and includes most of the important literature on the subject.

Various joints are dealt with, but by far the greatest portion of the discussion is given to hip joint arthroplasty with the author submitting an evaluation of his own as well as other surgeons' results. His enthusiasm for the stem prosthesis with an acrylic head is not shared by a large number of orthopedic surgeons in the United States.

The chapters on the principles of postoperative treatment and rehabilitation are reasonably complete. The instructions are rather general and will be most helpful to those who are already acquainted with the trials encountered in the postoperative management of the reconstructed joint.

This monograph is recommended reading for orthopedists especially interested in the history of arthroplasty. The remainder makes interesting reading but falls somewhat short of being a classic reference work in the field.—CLIFFORD A. STEVENSON, Capt., MC, USN

JOINT LIGAMENT RELAXATION TREATED BY FIBRO-OSSEOUS PROLIFERATION, by George Stuart Hackett, M. D. With special reference to low back disability, trigger point pain and referred pain. 97 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$4.75.

The author has presented in monograph form his views on the anatomy, etiology, pathology, diagnosis, and treatment of painful joints. Based on 16 years of experience in therapy, including administration of over 3,000 injections, he has concluded that both local and referred pain in low back disability and in that of other joints is due to ligamentous instability. The methods of accurate diagnosis and localization of the trigger points are clearly described and stressed. Phe-

nominal cures of all these conditions were obtained by the injection of these trigger points with a fibro-osseous proliferant, a wonderful procedure if it can be reduplicated by other physicians treating the same type of conditions.

The author has very adequately expressed his views and presented convincing evidence to support the soundness of his treatment but at times is repetitious. The book is satisfactorily illustrated with 17 black-and-white and line drawings.

The author has assumed that all physicians ignore the anatomy, function, and treatment of injuries to the ligamentous structure of joints. Although this may be an extreme view, too often the adequate treatment for ligamentous injuries is neglected. This results in complications which are considered and treated as separate entities without due regard to their primary cause.

This book should be read by every physician and be available for ready reference to every physician who treats the residuals of joint trauma.—JOSEPH W. BATCH, Col., MC, USA

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. Preventive Medicine in World War II. Volume III: Personal Health Measures and Immunization. 394 pages; illustrated. Prepared in the Historical Unit, Army Medical Service, Editor-in-Chief, Colonel John Boyd Coates, Jr., MC. Editor for Preventive Medicine, Ebbe Curtis Hoff, Ph. D., M. D. Office of the Surgeon General, Department of the Army, Washington, D. C., 1955. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price \$3.25.

This third volume in the series on "Preventive Medicine in World War II" covers the general field of health measures and immunization. The subject is broken down into chapters dealing with manpower selection, *personal hygiene, clothing, nutrition, malnutrition and deficiency diseases, preventive psychiatry, accidental trauma, and immunizations.*

The authors have, in narrative fashion, detailed the experiences, mistakes, and repetitive efforts of the past in relation to these various aspects of personal health measures. Each chapter is a condensation of a mass of reference material boiled down sufficiently to prevent the reader from becoming mired in detail. For those who wish to study the subject of each chapter in more detail the source material is listed accurately at the foot of each page.

Here in one volume reposes a wealth of information on the trials, errors, and accomplishments of the past which, but for their compilation in this book, would be lost to those responsible for planning for the future. Whether read by military or civilians, all of the chapters are interesting, and some are fascinating, not only in content but in style.

The chapter on clothing is introduced by an explanation of the physics and physiology involved in the control of temperature and

humidity problems as related to the body. A thorough understanding of this chapter by all medical and line officers will eliminate in the future much of the effective time lost in past wars from such related injuries as trench foot.

If this volume had not been compiled, it is conceivable that many of the mistakes of the past war would be repeated for lack of a single source of material on these subjects. In most chapters the experiences and developments are discussed in general and also in relation to war theaters. This is of additional aid to those seeking guidance in developing a global preventive medicine program.

—LESTER P. VEIGEL, Col., USAF (MC)

THE YEAR BOOK OF DRUG THERAPY (1955-1956 Year Book Series), edited by Harry Beckman, M. D. 560 pages; illustrated. The Year Book Publishers, Inc., Chicago, Ill., 1956. Price \$6.

This yearbook, published each January, is based on the material in journals received through the preceding August.

The book is divided into sections on antibiotics and sulfonamides, cardiovascular diseases, surgery, et cetera, and within each section articles concerning new drugs, new information about old drugs, or new therapeutic approaches to particular diseases are abstracted. Editorial footnotes call attention to particularly notable deficiencies of or value in the articles abstracted in an attempt to tie isolated findings together and to give a more complete therapeutic concept. Articles reinforcing or contradicting each other are frequently reviewed together editorially.

This format plus a good index make this book the best available reference or review. Its yearly publication ensures current information, and the large number of both domestic and foreign journals reviewed guarantees coverage of any particularly important innovations. The book should be in all medical libraries and is heartily recommended to all physicians, from internes to specialists.

—CHRISTIAN GRONBECK, Lt. Col., MC, USA

DISEASES OF THE LIVER, Edited by Leon Schiff, M. D., Ph. D., with the collaboration of 27 contributors. Foreword by Cecil J. Watson, M. D., Ph. D. 738 pages; illustrated. J. B. Lippincott Co., Philadelphia, Pa., 1956. Price \$16.

Advances in our knowledge of the liver, its diseases and their treatment, have been sufficient to warrant compilation in this sizable volume. The most important recent developments are said to be in the following fields: (1) knowledge of basic structure and function of the liver, (2) experimental production of liver disease, (3) viral hepatitis, (4) hepatic coma and nitrogen metabolism, (5) pathogenesis and treatment of cirrhosis, (6) treatment of hemochromatosis by phlebotomy, (7) copper metabolism in Wilson's disease, (8) needle biopsy of the liver, and (9) surgery for portal hypertension. Twenty-eight eminent workers have written on those aspects of liver disease in which they are well-

known experts. No single author could authoritatively cover all of this material before it became history. Dr. Schiff has so skillfully edited this book that it presents a balanced and thorough treatment of the subject, covering all important features without the omission of significant areas.

The gross and microscopic anatomy, physiology, and biochemistry of the liver are considered in 92 pages, followed by a chapter on experimental hepatic injury and three chapters on diagnosis and diagnostic tests and methods. The remaining 500 pages are devoted to disease entities and syndromes.

The focus of the book is predominantly clinical, and with few exceptions the contributors are persons whose daily activities devolve around the diagnosis and treatment of patients with liver disease. This book will be an extremely useful tool for anyone concerned with patients who have hepatic disease.

—BENJAMIN H. SULLIVAN, Jr., Col., MC, USA

A MANUAL OF FRACTURES AND DISLOCATIONS, by *Barbara Bartlett Stimson*, M. D., Med. Sc. D. 3d edition. 224 pages; 97 illustrations. Lea & Febiger, Philadelphia, Pa., 1956. Price \$4.50.

This book is a brief introduction to the subject of fractures and dislocations. It is written in an informal style with proper emphasis on conservative treatment of fractures, and occasionally indications are given for more radical intervention. The book is divided into a section on general treatment principles, followed by sections related to anatomic distribution of injury. Line drawings which are concise and clear are used as illustrative material, but methods mentioned in the text are not in all instances illustrated. This is especially true of the management of fractures by traction, and this discrepancy would lead to error unless other texts were used. Each fracture is briefly discussed as to diagnosis, etiology, incidence, treatment, and prognosis. It must be said, however, that in most instances the prognoses in patients with fractures are somewhat optimistic, and periods of immobilization for joint dislocations are unusually short. It is stated that a dislocated shoulder, for instance, need only be immobilized by a sling and swathe for a few days. This small text could serve well as an introduction to the treatment of fractures and dislocations for medical students and could be used as a guide for instruction. However, confronted with the problem of management of any specific fracture, one could hardly find enough material in this book and would be forced to seek other sources for guidance in definitive management.

—STERLING J. RITCHEY, Col., MC, USA

DISEASES OF THE LIVER AND BILIARY SYSTEM, by *Shelia Sherlock*, M. D. (Edin.). 720 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1955. Price \$10.

In this clear and practical guide to hepatic and biliary disorders, the author, an experienced authority, has used the functional approach. Throughout, the emphasis is on the disturbance of liver (and biliary)

function, yet the laboratory is kept in proper balance with bedside observation.

There are numerous excellent illustrations, and the large type and attractive use of bold and italic faces make this book exceptionally easy to read.

A special word of thanks should be offered Dr. Sherlock because she has managed to describe a subject of great complexity with admirable simplicity. In fact, American authors could learn a great deal from a study of this model of English medical literature.

Because of the interrelations between the liver and all metabolic disturbances and because of the many types of primary and secondary hepatic disturbances the discussions are, in many instances, relatively brief. Nevertheless practically all the essential information is presented. Therefore, this book will certainly appeal to the student, house officer, and practitioner. The research investigator would use the book for a handy reference, although he may have to refer to experimental papers for certain details. The text can be strongly recommended to all readers.—S. O. WAIFE, *Lt. Comdr., MC, USNR*

AN ATLAS OF OTOLARYNGIC PATHOLOGY. By Colonel J. E. Ash, USA (Ret.), M. D., and Muriel Raum, M. D., Published under the joint sponsorship of the American Academy of Ophthalmology and Otolaryngology, The American Registry of Pathology, and The Armed Forces Institute of Pathology. 572 pages; 2,024 figures on 420 plates. American Registry of Pathology, Washington, D. C., 1956. Price \$20.

This is an extensive volume that covers a variety of lesions found in the general field of pathology in addition to diseases of the respiratory tract, neck, and ear. The format of the book is excellent, and for the most part the many black and white photomicrographs are clear and readily understandable.

The first part is devoted to a section on general pathology and presents a variety of subjects such as inflammation, pigmentation and degeneration, deficiency diseases, miscellaneous diseases of bone, and dermatoses. This section, I believe, could be deleted as it is adequately covered in the texts of general pathology readily available. However, on the whole the field of otolaryngic pathology is more extensively covered than could be found anywhere else. The plates on diseases and tumors of the ear are particularly good and well documented. This book will be a ready reference to the general pathologist as well as the otolaryngologist.—VERNON E. MARTENS, *Capt., MC, USN*

ROENTGEN INTERPRETATION OF FRACTURES AND DISLOCATIONS, by Joseph Levitin, M. D., and Ben Colloff, M. D. 265 pages; illustrated. Charles C Thomas, Publisher, Springfield, Ill., 1956. Price \$8.50.

In this first edition, a roentgenologist and an orthopedic surgeon have collaborated to produce a precise and practical guide to the reduction and immobilization of fractures. The title of the book is somewhat misleading. As stated in the foreword, the main purpose of the book is to

describe what constitutes generally accepted satisfactory reduction with emphasis on the important alinements to be restored or preserved as an aid to the roentgenologist.

The book serves as a handy reference of the essential normal x-ray anatomy of the more common sites of fracture and dislocation, the deformities usually produced by fracture or dislocation, the accepted position of reduction, and the usual time of immobilization. Methods of reduction, means of immobilization, and x-ray evidence of healing progress or complications are not included, except for several reproductions of roentgenograms demonstrating normal and abnormal healing progress in fractures of the femoral neck.

Aside from the 16 reproductions of hip roentgenograms, the parts are represented by diagrams which include only the essential anatomy and which are adequately labeled. Several errors in labeling are noted. Approximately 50 per cent of the text is devoted to the diagrams. Fractures of the skull and facial bones are not included. Fractures and dislocations of the spine are treated rather sketchily in a total of 18 pages as compared to 10 pages devoted to traumatic dislocation of the hip. Included as Appendix A are two pages of "bone age charts." Appendix B consists of five pages of line drawings of common appliances used in internal fracture fixation.

Although this volume is not intended as a complete reference book, it adequately serves the limited purpose intended by the authors.

—DELL F. DULLUM, Col., MC, USA

CLINICAL ELECTROCARDIOGRAPHY, Part 1, The Arrhythmias, With an Atlas of Electrocardiograms, by Louis N. Katz, M. D., and Alfred Pick, M. D. 737 pages; 415 illustrations. Lea & Febiger, Philadelphia, Pa., 1956. Price \$17.50.
